Tetany—It must be remembered that tetany is merely a symptom complex of increased neuromuscular irritability. Gastric tetany from loss of gastric secretion, or tetany due to overventilation, has little to do with calcium deficiencies but is due to an alkalosis. Measures designed to increase calcium metabolism are not indicated here. Parathyroid extract exerts its outstanding value in the treatment of acute or postoperative low calcium tetany. The removal of parathyroid glands may occur of course during a total or subtotal thyroidectomy as well as during a parathyroidectomy. Under such conditions, tetany may appear between sixteen hours and six days after the operation. Usually preceded by tingling and numbness, often with a feeling of nervousness and fright, the signs may rapidly become intense and fulminating. Carpopedal spasm, severe laryngeal spasm, and generalized convulsions associated with great cyanosis may develop and require most careful therapy if death is to be avoided. The drugs that are available must be chosen with attention to their speed and duration of effectiveness. The slow intravenous injection of calcium salts has an almost instantaneous beneficial effect, which often lasts longer than two hours. Calcium gluconate is an excellent salt for this purpose because it does not cause sloughing, as would calcium chloride, if it escapes about the vein. In the normal adult 10 cc of a 20 per cent solution of calcium gluconate may be given intravenously if at least four minutes is taken for the injection, a few minutes later a similar amount may be injected intramuscularly. The relief from low calcium tetany by this procedure is dramatic, and if necessary the procedure may be repeated on the return of the tetany. For a more prolonged effect one must turn to parathyroid extract, which, after its four hour latent period, will elevate the blood calcium for nearly twenty hours. These two drugs—calcium by mouth, and parathyroid extract intramuscularly—can maintain the patient free from tetany for many weeks, and if necessary the rôle of parathyroid extract may be taken over gradually by large doses of vitamin D. It must not be forgotten that thyroid extract also mobilizes calcium stores and is therefore an aid in the therapy of this disease.

Other suggested uses of parathyroid extract are dependent on the desirability of (a) decalcifying the body and (b) raising blood levels and excretion of calcium.

The desire to have the body lose calcium occurs (1) when there are abnormal deposits of calcium salts in

the tissues and (2) when there are abnormal metals stored in the bone, as in lead or radium poisoning.

1 Many attempts have been made to decalcify the abnormal deposits of calcified glands, arteriosclerosis, otosclerosis and myositis ossificans. While an occasional positive result is reported, most of these attempts have resulted equivocally. The reason for this is now clear, for it is the supply of calcium and phosphorus stored in bones that is drawn on first in times of demand. The trabeculae of bone, scattered throughout the marrow, act as a readily available supply that can store or liberate calcium, much as fat stores are available for calories. As a result of this excellent physiologic mechanism, the calcium in the abnormal deposits is not disturbed. Therefore it does not appear to be a practical procedure to attempt decalcifying therapy for any of these conditions.¹

2 Because of the ready liberation of bone salts it is clear that one can use a decalcifying regimen to liberate abnormal metals which may be stored in bone. Lead is the prototype of such metals, and probably the most effective method of removing lead from bones is by means of a low calcium diet plus parathyroid extract.² Flinn and Seidlin³ have reported similar results for radium. Two factors in the procedure must be remembered. 1. An acid-producing salt, such as ammonium chloride, is easier to use clinically, even though slower in effect, and eventually probably has the same result. 2. Because the bone trabeculae are first drawn on, the abnormal deposits of metal that may be in the bone cortex will be affected only slightly.⁴ With an inert metal like lead, it is more important to eliminate the portion stored in the trabeculae.⁵ With a metal such as radium and its derivatives, however, which injures the surrounding tissues by its continuous bombardments with rays and particles, the part that remains in the bone cortex is of considerable importance, and this is not readily influenced by any known therapy.

RAISING THE BLOOD CALCIUM LEVEL

Raising the blood calcium level should theoretically be of clinical value in the healing of fractures. There has been some difference of opinion about this,⁶ though it now appears evident that little benefit can be expected from this type of therapy. Nor do I think much delay in ossification could occur from the use of parathyroid extract, because callus as well as ossifying cartilage has such an affinity for holding calcium. A recent severe hyperparathyroidism in a growing boy has demonstrated that decalcification occurs in all the bones except about the areas of ossification.⁷ It appears, therefore,

7 Tibbets D, McLean R and Aub J C. Unpublished data.

that according to present evidence parathyroid extract would exert little influence on the healing of fractures

While an adequate calcium and phosphorus intake, together with viosterol, is probably of value in the control of dental caries, it would appear obvious that the more difficult use of parathyroid extract would not be indicated in this regard

There are many other conditions in which high calcium therapy has been declared of value. Only two of these need to be discussed here—pregnancy with lactation, and edema

Pregnancy with lactation has great effects on the calcium stream in the body. This was dramatically demonstrated by the observations of Kozelka, Hart, and Bohstedt,⁸ in which they showed that adult thyroparathyroidectomized dogs lived satisfactorily when given 13 rat units of vitamin D daily until they became pregnant. Their requirements for vitamin D to prevent tetany then gradually rose to 26,000 units, and during lactation to more than 40,000 units daily. It is not difficult, therefore, to understand the appearance of tetany and the bodily need for high calcium therapy and its adjuncts during this period. In a prolonged demand such as this, the control of tetany can usually be accomplished by the wise use of adequate amounts of milk and vitamin D. Only rarely will the more urgent treatment of tetany, already described, be needed

Edema—Parathyroid extract has been advised to reduce the edema of acute and chronic nephritis,⁹ of nephrosis,¹⁰ and also of cardiac failure.¹¹ Some investigators have found that persistent edema responded well to the daily injection of 250 units of parathyroid extract for a few days. This therapy corresponds to the good reports of other investigators following the use of calcium salts. While the difficulties associated with injections of parathyroid extract remain a deterrent factor in their use in edema, this method of therapy should not be neglected. In cases resistant to other forms of therapy, parathyroid extract may well be tried

Parathyroid extract has also been recommended in asthma and vasomotor rhinitis, in hemorrhage, in jaundice, and in gonorrheal epididymitis and salpingitis, but its use in these conditions has not been adequately established

SUMMARY

The chief therapeutic value of parathyroid extract is dependent on its influence on the blood levels of calcium and phosphorus. Its major use, therefore, lies in the treatment of acute low calcium tetany. In this condition it may be a life saving measure. Parathyroid extract may also be chosen for other therapeutic purposes. In these less urgent conditions, its beneficial effect arises from the liberation and the increased excretion of salts derived from bone

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT

HOWARD A. CARTER, Secretary

CAPSON BABY'S NURSING BOTTLE STERILIZER ACCEPTABLE

Manufacturer: Capson Manufacturing Company, 4115-4121 Ravenswood Avenue, Chicago

Sterilizing baby's nursing bottles is accomplished by live steam at approximately atmospheric pressure with this device.

The Capson Sterilizer consists of an inverted pan (12 inches in diameter) approximately 1 inch in depth with seven aluminum tubes projecting upward approximately 2 inches, and a kettle about 14 inches deep. The rack and tubes are placed in the deep kettle containing clear water. One half inch of water is sufficient to allow space under the tubes for the steam to collect. The kettle is deep enough to permit the bottles to stand upright. Bottles are inverted over the steam tubes and are held in place by a guide. After the cover has been placed on the deep kettle, it is placed over a source of heat. Live steam circulates in the inverted bottles, and the surface of the bottle, including the neck and outside, are sterilized.

Capson Sterilizer

The Capson Sterilizer is made in two models, Model A being entirely of aluminum and Model B having aluminum tubes. The rack with the inverted pan and bottle rest are made of heavily coated tin plate.

According to the firm, the reason for devising this unit is to do away with sterilizing baby bottles in large volumes of water, which requires that the bottles be completely submerged, and a long time over a source of heat is required to bring the water to a boiling point. Furthermore, in some localities, when the bottles are removed from the boiling water, a deposit is invariably found in the bottles, usually white but sometimes red, depending on the mineral contents of the water. This deposit, although sterile, is objectionable to the eye, and the manufacturer claims that it probably forms a splendid base for bacteria. In using the Capson Sterilizing method, the bottles are rinsed after use and inverted over the tubes, and the sterilizer is set into the deep kettle. When the water comes to a boil, live steam circulates in and around the bottles, sterilizing them and leaving no deposit. Ten minutes' boiling time is required to sterilize the bottles effectively. The nipples may also be sterilized by confining them in a small bottle made for the purpose. This bottle is inverted over one tube in the same manner as the nursing bottles.

In a laboratory acceptable to the Council, the Capson Baby's Nursing Bottle Sterilizer was investigated. The purpose of the test was to determine the efficacy of the Capson Nursing Bottle Sterilizer when confined within a large kettle. The objects were (1) to determine whether the apparatus sterilizes the inner surface of the nursing bottles, (2) to determine whether the lip and outside of the necks of the nursing bottles are sterilized, and (3) to determine whether the inner surface of the nipple jar, metal funnel-cap and nipples are sterilized.

Cultures used for test were stock strains of *Staphylococcus aureus*, *B typhosus* (*Eberthella typhi*) and *B coli* grown in broth twenty-four hours diluted 1:10 for use. Contamination was performed by smearing 2 cc of the diluted cultures over the inside of 8 ounce narrow-mouth nursing bottles and 2 cc over the lip and outside of the neck and by running 2 cc of each suspension into the nipple jar containing the nipples, in such a manner that the funnel, the inside of the jar and the nipples were soiled.

The Capson Sterilizer with bottles, nipples and jar were placed in a covered kettle, containing about one-half inch of water and were steamed ten minutes.

Controls consisted of boiling for twenty minutes in water in a covered boiler a parallel set of contaminated bottles and nipples.

After "sterilization" tests for sterility were made by (a) flushing the outside of the neck and lip of the bottle with a tube of broth, (b) flaming the mouth of the bottle, pouring in a tube of broth then plugging the bottle with sterile cotton and flushing the inside of the bottle with the added broth, (c) placing the nipples in flasks of broth, and (d) flushing the inside of the nipple jar with broth and then pouring broth into a sterile test tube. The broths were then incubated for forty-eight hours. Tests were also run, in which diluted cultures with sterile milk were used instead of salt solution.

B. subtilis, which is a spore-bearing organism resistant to sterilization, was introduced as a trial organism to test the effectiveness of the sterilizer without the expectation of success, for autoclaving is the only certain heat method for killing spores. The results while not successful, compare favorably with the control boiling method according to the limited number of experiments performed. The tests in which the contaminated utensils were permitted to dry and in which milk dilutions of the organisms were used were designed to approximate actual conditions that might eventuate.

Within the scope of these experiments the Capson Nursing Bottle Sterilizer as modified, by operating within a covered pail and by the nipple jar seating on the spout, is an effective and practical method for sterilizing nursing bottles and nipples.

This Sterilizer will effectively sterilize only when it is confined within a deep kettle and the cover placed on it. In view of the favorable report as to the efficacy of this sterilizer, the Council on Physical Therapy voted to include the unit in its list of accepted devices.

TOMAC OXYGEN INSUFFLATOR ACCEPTABLE

Manufacturer American Hospital Supply Corporation, Chicago

The Tomac Oxygen Insufflator is a portable tracheal apparatus for the administration of oxygen. The outfit is small and compact, weighing less than 15 pounds, which provides for easy removal to the bedside of a patient or wherever needed.

Over-all dimensions are 8¼ inches high by 9 inches wide by 7 inches deep. All gages and the regulator are set in a black bakelite panel and mounted at the eye level when in use. The entire unit is made of stainless steel, equipped with a carrying handle mounted on top. All inside parts are silver soldered. The unit has a visible water gage at the left of the regulator, a hose connection at the rear, and is equipped with a Tomac flow gage and Tomac pressure gage.

A regulator, which reduces 2,000 pounds per square inch pressure with safety and makes possible constant and controlled volume and pressure, is part of the equipment. The unit is also equipped with a pop-off valve as a means of safeguarding the patient and the operator against building up dangerous back pressures of oxygen. It has a maximum flow of oxygen of 15 liters per minute.

The Tomac Oxygen Insufflator was used in a clinic for a period of eighteen months and compared with other types of insufflators. The humidifier was found to deliver 20 mg or more of water per liter over the therapeutic range of 5 to 15 liters per minute. The water gage is designed so as to indicate clearly the upper and lower levels of water that are necessary to saturate the oxygen. The water trap has a capacity much over that of the humidifying chamber.

In view of the efficiency, durability and good performance of the Tomac Oxygen Insufflator, the Council on Physical Therapy voted to include the unit in its list of accepted devices.

Tomac Oxygen Insufflator

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS LEECH, Secretary

AZOCHLORAMID—A product containing approximately 96 per cent of N,N-Dichloroazodicarbonamidine.— $(\text{H}_2\text{N}(\text{ClN})\text{C}=\text{N}-\text{N}-\text{C}(\text{NCl})\text{NH}_2)$ —An N-chloro derivative of azodicarbonamidine.

Actions and Uses—Similar to those of chloramine, dichloramine, and solution of chlorinated soda, over which it is claimed to have an advantage in that it possesses lower reactivity with extraneous organic matter and higher bactericidal activity in the presence of organic material. Solutions of azochloramid are proposed for dressing, packing or irrigating infected wounds and cavities. Internal use of azochloramid solutions is not recommended. The available evidence indicates that the substance possesses a relatively low toxicity.

Dosage—Azochloramid is usually employed in concentrations of 1,600 and 1,300 in approximately isotonic buffered saline solutions. A solution containing one part of azochloramid in 500 parts of glyceryl triacetate (triacetin) and possessing greater stability than the aqueous solutions may also be used.

Manufactured by Wallace & Tiernan Products, Inc. Belleville, N. J. U. S. patents 1,958,370 (May 8, 1934, expires 1951) and 1,958,371 (May 8, 1934, expires 1951). U. S. Trademark.

Azochloramid Buffered Saline Mixture (for preparing 1 liter of a 1:3,300 aqueous solution). Vials containing azochloramid 0.3 Gm., sodium phosphate 0.6 Gm., potassium phosphate (monobasic) 0.09 Gm. and sodium chloride 8.5 Gm.

Azochloramid Buffered Saline Mixture (for preparing 1 gallon of a 1:3,300 aqueous solution). Vials containing azochloramid 1.14 Gm., sodium phosphate 2.27 Gm., potassium phosphate (monobasic) 0.34 Gm. and sodium chloride 32.18 Gm.

Azochloramid Buffered Saline Mixture (for preparing 1 liter of a 1:1,600 aqueous solution). Vials containing azochloramid 0.6 Gm., sodium phosphate 0.6 Gm., potassium phosphate (monobasic) 0.09 Gm. and sodium chloride 8.5 Gm.

Azochloramid Buffered Saline Mixture (for preparing 1 gallon of a 1:1,600 aqueous solution). Vials containing azochloramid 2.27 Gm., sodium phosphate 2.27 Gm., potassium phosphate (monobasic) 0.34 Gm., and sodium chloride 32.18 Gm.

Azochloramid occurs in bright yellow needles or plates. It possesses an odor suggestive of chlorine and has a burning taste. When pure it is odorless and practically tasteless. It is very slightly soluble in water, slightly soluble in glycerol and ether, soluble in alcohol, soluble (incompletely) in glacial acetic acid, acetone and ethyl acetate, very slightly soluble in chloroform and nearly insoluble in carbon tetrachloride and liquid petroleum. Azochloramid decomposes (explosively) without melting at 155.0–155.5 (U. S. P. X Melting Point Method). Solutions of azochloramid decompose on exposure to light.

Agitate 0.01 Gm. of azochloramid with 35 cc. of water a practically complete solution (yellow-orange) occurs with only a very slight turbidity at most. Treat 5 cc. portions of this solution as follows: Add 0.25 cc. of silver ammonium nitrate solution a brick red precipitate forms soluble in an excess of ammonia water, add 2 cc. of potassium iodide solution and agitate with 0.5 cc. of chloroform the chloroform layer is colorless or at most very faintly colored, add 0.1 cc. of diluted hydrochloric acid to the mixture and further agitate the chloroform layer acquires a deep violet color, add 2 cc. of diluted nitric acid solution and 1 cc. of silver nitrate solution a slight white turbidity but no precipitate forms, add sulphurous acid solution until the yellow color disappears, add 2 cc. of diluted nitric acid solution and 1 cc. of silver nitrate solution and agitate a curdy white precipitate remains soluble on addition of excess ammonia water, add from 30 to 40 cc. of water and treat according to the U. S. P. X turbidimetric test for chlorides, the turbidity is less than that produced in a control test made with 0.1 cc. of fiftieth normal hydrochloric acid.

Dissolve about 0.1 to 0.15 Gm. of azochloramid accurately weighed in 20 cc. of glacial acetic acid in a glass stoppered 250 cc. erlenmeyer flask. Add 10 cc. of potassium iodide solution and 50 cc. of distilled water, allow the mixture to stand for ten minutes and titrate the liberated iodine with tenth normal sodium thiosulphate. The number of cubic centimeters of tenth normal sodium thiosulphate consumed per gram (due to active chlorine and the azo group $-\text{N}=\text{N}-$) is not less than 317 cc. nor more than 328 cc.

Dissolve from 0.12 to 0.15 Gm. of azochloramid accurately weighed, in 15 cc. of glacial acetic acid contained in a 400 cc. beaker, add 90 cc. of water with stirring and follow with sufficient sulphurous acid solution to produce a clear colorless solution. Add 20 cc. of silver nitrate solution and 20 cc. of diluted nitric acid solution. Heat the solution until it boils and set aside for several hours. Filter through a prepared Gooch crucible and wash the precipitate well with portions of hot water slightly acidified with nitric acid, wash with one portion of cold water dry at 105°C. for one and one-half hours, cool and weigh the chloride (Cl^-) calculated from the silver chloride weighed is not less than 38.25 per cent nor more than 38.75 per cent.

Heat from 0.2 to 0.3 Gm. of azochloramid accurately weighed for five hours at 100°C. the loss in weight is not less than 0.4 per cent nor more than 0.7 per cent. Heat about 0.25 Gm. of azochloramid accurately weighed in a platinum dish until constant weight is attained, the ash is less than 0.1 per cent.

Committee on Foods

THE COMMITTEE HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
RAYMOND HERTWIG, Secretary

AMENDMENT OF COMMITTEE DECISION "FORTIFICATION OF FOODS OTHER THAN DIETARY STAPLES WITH VITAMIN D"

The second paragraph of the respective Committee Decision (THE JOURNAL, Feb 16, 1935, p 563) has been amended to include cake, cake flour, cheese and beer as examples of foods not warranting fortification with vitamin D. The amended paragraph will read:

"Examples of foods not warranting fortification with vitamin D are beer, cake, cake flour, cheese, ice cream and sausage, and such accessories as chewing gum."

ACCEPTANCE WITHDRAWN

ORANGE CRUSH CARBONATED BEVERAGE

Manufacturer—Orange-Crush Company, Chicago

Description—Carbonated beverage prepared from carbonated water, sucrose, orange juice (one twentieth by volume of the beverage), citric acid (lemon juice), sodium benzoate (0.05 per cent), orange oil and United States Department of Agriculture certified color.

Manufacture Analysis and Vitamins—See announcement, THE JOURNAL, March 31, 1934, page 1004.

Reasons for Withdrawal of Acceptance—Orange Crush Beverage was accepted on condition that all advertising would appropriately present the product as a beverage containing little orange juice and prominently display a complete descriptive statement defining the article. The name Orange Crush, unless appropriately qualified in each individual piece of advertising, incorrectly implies that the product is either all orange juice or essentially orange juice. In fact, only one twentieth by volume of this beverage is orange juice.

The company subsequent to acceptance did not demonstrate compliance with these requirements in respect to advertising apart from the label. The advertising continued to present the product as "Orange Crush." After approximately one year the company found that competitive advertising practices in the field of beverages would not permit the successful merchandising of Orange Crush Beverage in accordance with Committee requirements for advertising and requested withdrawal of acceptance.

Names and advertising for beverages should correctly inform the public of the nature and food value of beverages it purchases. Any name or advertising that may lead the consumer to believe a beverage containing little fruit juice is essentially or in considerable part fruit juice is seriously misleading. Orange juice and Orange Crush Beverage are distinctive products with wholly unlike nutritional values. Orange juice is a rich source of vitamin C, whereas Orange Crush Beverage contains only an insignificant quantity.

The bottle label for Orange Crush Beverage comes within the jurisdiction of the federal Food and Drugs Act and is satisfactory for informing the consumer. This law however, unfortunately does not govern food advertising apart from package labels.

Under these conditions the public has no legal protection from false and deceptive advertising. Beverages and other foods may be advertised in a false and deceptive manner with respect to composition and food values without legal interference.

In that the company finds itself competitively unable to advertise Orange Crush Beverage in accordance with the Rules and policies of the Committee on Foods for truthful advertising, acceptance is being withdrawn and the product will no longer be listed among the accepted foods of the Committee on Foods.

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

RAYMOND HERTWIG, Secretary

MOUNT ROYAL DAIRIES PASTEURIZED HOMOGENIZED MILK

Distributor—Mount Royal Dairies, Ltd., Montreal, Canada.

Description—Bottled, pasteurized, homogenized milk.

Preparation—Milk obtained from producers licensed by the Montreal Board of Health and subject to the requirements of the Province of Quebec is regularly tested for milk fat, bacterial content and its reaction to methylene blue. A rigid inspection is also maintained in the dairy's own laboratory. Milk passing these tests is heated to 63 C, filtered at 49 C, homogenized under 2,500 pounds pressure, pasteurized by the holding method (63 C for thirty minutes), cooled to 3 C and automatically filled in bottles by the usual procedure (THE JOURNAL, Sept 1, 1934, p 681).

Analysis—Standardized to contain not less than 37 per cent of milk fat.

Calories—0.7 per gram 20 per ounce.

Claims of Distributor—The cream does not separate. The curd formed in the stomach is softer than that from unhomogenized milk.

KISMET CAKE FLOUR

Manufacturer—Noblesville Milling Company, Noblesville, Ind.

Description—Short patent flour prepared from soft winter wheat bleached and matured.

Manufacture—Soft winter wheat is cleaned, scoured, tempered and milled by essentially the same procedure as described in THE JOURNAL, June 18, 1932, page 2210. Chosen flour streams are blended, bleached with a mixture of benzoyl peroxide and calcium phosphate (one-half ounce per barrel), matured with beta chloral (2 ounces per barrel), and packed in paper sacks.

Claims of Manufacturer—Recommended for cake and pastry baking.

CELLU APPLE SAUCE PACKED IN WATER WITHOUT ADDED SUGAR OR SALT

Distributor—The Chicago Dietetic Supply House, Inc., Chicago.

Packer—Geneva Preserving Company, Geneva, N. Y.

Description—Canned cooked apple sauce prepared from peeled and cored apples packed in water without added sugar or salt.

Manufacture—New York State Baldwin or Greening apples are automatically peeled, cored, trimmed, inspected, immersed in cold salt solution to arrest enzymatic action, again inspected for removal of bruised sections, particles of cores and any other defects, are cooked in an atmosphere of steam, screened and automatically filled into cans, which are sealed, processed for about ten minutes in boiling water and immediately cooled.

Analysis (submitted by distributor) —

	per cent
Moisture	89.4
Total solids	10.6
Ash	0.2
Fat (ether extract)	0.3
Protein (N X 6.25)	0.3
Reducing sugars as invert sugar	6.1
Sucrose	1.5
Crude fiber	0.8
Carbohydrates other than crude fiber (by difference)	9.0

Calories—0.4 per gram 11 per ounce.

Claims of Distributor—For diets in which sweetened fruit is proscribed.

PROLONGATION OF HUMAN LIFE

The obituary notices regularly published in *THE JOURNAL* offer data that should make the physician pause in his professional treadmill and reflect on his own mode of living. A list of 100 deaths of physicians was made up from the notices in *THE JOURNAL*. Suicides and accidental deaths were excluded. In this group 65 per cent died of cardiovascular disease, the youngest died at 37 of carcinoma, the oldest physician, aged 89, died of cardiac failure. The average age of this small group was 64 years. In the registration area of the United States in 1928, cardiovascular disease caused the death of 45.5 per cent of those over 45 years. Allowing for the smallness of the group of physicians studied, the percentage of deaths from cardiovascular disease is still excessive. The anxieties and stresses of medical practice, irregularities in dietary habits, the disturbed rest and the multifarious activities of a busy practitioner tend to exhaust the cardiovascular apparatus. Comparative anatomists have established that the natural life expectancy of an animal is usually five times the period needed for full skeletal development. Since 21 years is required for full skeletal growth in man, the age of 105 might be set as the approximate normal human limit.

Montaigne said "Men do not usually die, they kill themselves." During the past century there has been a substantial increase in the general life expectation as the result of modern advances in hygiene and sanitation. Most of the progress has been achieved in infant and young life. Little has been accomplished in the improvement of health and mortality in older persons. Under present conditions, thirty-three out of every hundred thousand people in the United States may expect to live 100 years. Most people fall by the wayside between 60 and 80 years of age. At the later periods of life the mortality is chiefly due to degenerative diseases such as arteriosclerosis, chronic nephritis, heart disease and cerebral hemorrhage. Among numerous factors that may conceivably influence the health and life of the individual are heredity, diet, habits of work

and thought, pleasures, climate, economic status, social position, profession or occupation, race, and exposure to infectious diseases such as pneumonia, tuberculosis and syphilis.

Longevity may be considered from the broad point of view of the biostatistician, who deals with mass figures and considers the longevity of groups and strata of the population. Life expectancy during the Middle Ages is estimated at 21 years. During the eighteenth century in France, 29 years was the average expectation of life. In 1859 in the same country it was estimated at 40 years. The United States had a life expectancy of 48 years in 1915. In 1925 it was 55 years, and in 1926 it reached 57.74 years. Dublin¹ has studied the Massachusetts life tables from 1890 to 1930. He observed that the gains in expectation of life have been greater among females than among males. These gains decrease rapidly from decade to decade, until at the age of 40 they virtually disappear. There have been significant qualitative changes in mortality as studied during this forty year period. Certain diseases that ranked high in mortality forty years ago are not important now. Diseases that now assume a high position in the mortality list were not included at the beginning of the twentieth century. In the first five years of the century, tuberculosis led all other diseases by a large margin with a death rate of 184.7 per hundred thousand. By 1925-1929 this disease had fallen to sixth in rank, with a death rate of 77.2 per hundred thousand. Organic heart disease, which was third in order at the beginning of the century, is now the leading cause of death, with a mortality almost double that of thirty years ago. In only one respect has modern sanitation and medical science been able to effect any improvement in mortality from cardiac disease. There has been a considerable drop in death rate among children and in adults up to the age of 45, but in older ages the rate has greatly increased. The general aging of the population is in part responsible for the rise in the death rate from heart disease. Many who might have been victims of other diseases under previous conditions of sanitation now succumb at older ages to heart disease. Diphtheria has been almost completely eliminated, as the result of vigorous public health campaigns and the general use of toxoid. The most conspicuous example of a disease that has utterly disappeared as a leading cause of death is typhoid. This has been accomplished by the modern practice of sanitation and hygiene.

Although mass statistics indicate a definite upward trend in the duration of life, individual longevity is still problematic and the resultant of hereditary and environmental influences. Pearl,² who has studied longevity as a problem in biostatistics, states that the average

¹ Dublin, L. J. and Lotka, A. J. *The History of Longevity in the United States*. Human Biology 6: 43 (Feb.) 1934.

² Pearl, Raymond. *The Distribution and Correlation of Variation in the Total Immediate Ancestral Longevity*. Human Biology 6: 98 (Feb.) 1934.

value of this biologically important characteristic is constant for the particular species, variety or race. By a series of studies on the total immediate ancestral longevity (TIAL), which is the mean sum of the ages of death in the six immediate ancestors of an individual, Pearl concludes that the total immediate ancestral longevity is as definite a biologic attribute as the individual's height. He finds that the average longevity of ancestors in a group of nonagenarians and centenarians is greater than that of persons not selected for their longevity. It is of great interest that 13.4 per cent of this nonagenarian group was bred from matings in which neither parent was long lived. With respect to innate genetic longevity Pearl finds three large groups: those dying under 50 years of age, those dying between 50 and 70 years, and those dying after 70 years. In comparison with heredity, Pearl finds that environment is less potent a factor in determining longevity. Alexander Graham Bell³ studied the genealogy of the Hyde family (8,797 persons) to determine the conditions associated with longevity. He found that a tendency to longevity is an inheritable characteristic. In cases in which neither parent lived to be 80, only 5.3 per cent of the offspring lived to be 80 or older. When only one parent lived to be 80 or older, 9.8 per cent of the offspring survived to 80 or beyond. When both parents lived to be 80 or older, 20.6 per cent of the children lived to be 80 or older. The average duration of life of the progeny was greatest in cases in which the parents were long lived, least when they were short lived, and intermediate when the parents died at intermediate ages. There was a direct correlation between the duration of life in the parents and the longevity of their children. The younger the parents were at marriage, the greater was the average longevity of their progeny. Children born during the first ten years of married life were longer lived than those born later. Bell concluded that heredity is a most significant factor in determining longevity. Nakayama⁴ sent questionnaires to 10,000 octogenarians in Japan. He found that the majority of the aged had long lived grandparents, parents, brothers and sisters. They were found mostly in the middle classes. The lower classes ranked second as concerns longevity and the upper classes third. The majority proved to be the eldest son or daughter. Most of them were born when the fathers were between 26 and 30 years of age and the mothers between 21 and 25 years. Nakayama found that longevity was rare among the unmarried. The aged had an average constitution, but some were corpulent and a few were slender. Tall men lived long, but short individuals did not. As concerns personal habits, most of these old persons went to bed early and arose late. They usually had led a quiet life. Half of them were drinkers but the women were all nondrinkers. Nakayama concludes

that for long life it is necessary to come from long lived parents, preferably of the middle classes and located in rural rather than urban communities.

Longevity is an art as well as a science. The art consists in practicing a reasonable adaptation to environment and adherence to the laws of hygiene based on a knowledge of oneself and one's needs. The mental outlook is as important as the physical aspect of living. It is desirable to cultivate equanimity, contentment and optimism. All disturbing passions such as anger, envy and jealousy should be avoided. Diet is important in the maintenance of reasonable longevity. Authorities agree that the amount of food should be restricted in old age. Nevertheless a strict adherence to stringent rules of diet is not desirable, since it may become a neurotic fad. The progressive decline in the course of life is not an inexorable law. The tempo of the biochemical processes may be increased or diminished by modes of living. Modern high tension living and intense competition accelerate the rate of living and evoke premature senility, followed by premature death due to cardiovascular degeneration. Old age has been shelved as useless in a society based on material standards. This is erroneous. Consider the productivity and usefulness exemplified by the old age of Michelangelo, Titian, Luigi Cornaro, Gladstone, Edison and Jacobin. Emerson has said that men old in years and intellect have composed the greatest governments. As Thewlis⁵ suggests, old age is more beautiful and fruitful than is ordinarily supposed. Dr Abraham Jacobin was in active practice past the age of 87, after having practiced more than sixty-three years. He remained keen of intellect and memory and his advice was sought by many. The distinguished surgeon W. W. Keen wrote his system of surgery when he was past 70. Physicians should consider physiologic old age as a happy state worth achieving and should encourage the aged to carry on their work.

Geriatrics has been a neglected field of medicine. At present the mortality at advanced ages is considerably more than necessary, owing to neglect of special study in the anatomy and physiology of senescence. The tissues of the aged are vulnerable as in early life to childhood diseases such as thrush, bronchitis, chilblains, eczema and pneumonia. There is a tendency to develop growth irregularities such as warts, acne, nevi, moles and freckles. Gilford⁶ calls attention to the defective immunity that accompanies senile degeneration, with resulting susceptibility to bacterial invasion. The rate of senescence varies in different individuals and in various organs. The thymus gland dies in youth, the ovaries at about 48, and the testes around 65 years. In the rare condition of progeria, a person may be senile in early childhood and die of old age in adolescence. Similarly the flame of life may flicker much beyond the

⁶ Gilford. *Hastings The Disorders of Post Natal Growth and Development* 1911.

usual term. Many biochemical mysteries are involved in these phenomena, which challenge the curiosity and spirit of the scientific investigator. Elie Metchnikoff, an eminent student of longevity, has said: "Human life does not last as long as it ought to in ideal conditions. We may predict that when science occupies the preponderating place in human society that it ought to have, and when knowledge of hygiene is more advanced, human life will become much longer and the part of old people will become much more important than it is today."

CHEMICAL NATURE OF HEMATOPOIETIC SUBSTANCES PRESENT IN LIVER

The observation about nine years ago that liver contained a substance which when fed to patients with pernicious anemia produced a dramatic improvement aroused immediate interest regarding the chemical nature of the active substance. Chemical "dissections" of the complex hepatic material were undertaken in several laboratories and within a relatively short time information that gave considerable insight into the chemistry of the hematopoietic substance was reported.¹ The active agent did not appear to be a carbohydrate, lipid, protein, proteose, peptone, simple polypeptide, purine, pyrimidine or single amino acid. Apparently it was a nitrogenous base, perhaps a secondary or tertiary amine. Further evidence of the nitrogenous character of the substance was reported by another group of investigators,² their results, however, suggested that the active agent was probably a simple polypeptide.

In the five years since the completion of these pioneer investigations, progress in studies of the chemistry of the active hematopoietic substance has become increasingly difficult because the availability of effective anti-anemia preparations has lessened the number of satisfactory patients for the assay of the various chemical fractions. Also, experience has shown that many of the chemical methods of choice for the fractionation of the crude preparations cannot be employed because of the consistent inactivation of the product. However, within the past few months progress has been made, one group of investigators,³ has separated from potent liver extracts three substances that may prove of importance. Two of these were obtained in crystalline form, one was identified as *l*-tyrosine and the other was believed to be a complex purine. The identity of the third fraction had not been ascertained. Both the tyrosine and the purine derivative produced a marked reticulocytosis when administered to guinea-pigs, and the latter also exerted a favorable therapeutic

effect in canine black tongue. It should be borne in mind however, that the value of these two experimental animals as hematopoietic test subjects has not as yet been adequately determined. A recent comment⁴ on a report of the clinical trial of the three fractions states that none of them when used alone possessed clinical activity, whereas a mixture of the three was highly effective as a remedy for pernicious anemia. This work seems to indicate that several substances having a mutual supplementary action are responsible for the clinical value of liver in the treatment of pernicious anemia.

Meanwhile, a report of comprehensive chemical studies describing results considerably different from those just discussed has appeared.⁵ The chemical behavior of the active material isolated by Dakin and West resembled that of a derivative of a polypeptide. It was precipitated by Reinecke acid and could be salted out by ammonium sulphate, magnesium sulphate or sodium chloride. The clinical activity was readily destroyed by exposure to cold half-normal sodium hydroxide, by boiling for one hour with half-normal sulphuric acid, or by treatment with the salts of certain heavy metals. Some insight regarding the possible chemical composition of the substance was gained by studying the products obtained by the hydrolysis of relatively pure preparations. One of these products was an aminohexose, similar to glucosamine but not definitely identified as such. The amino acids lysine, arginine, glycine, leucine, hydroxyproline and aspartic acid were definitely identified in hydrolysates of the purest preparations. Pyrimidine and purine bases were absent and some active preparations contained practically no inorganic material. The possible molecular weight of the substance, as determined by a titration method, was found to be some multiple of 1,430, a value not unlike the values expected for polypeptides. As indicated by the rate of liberation of free amino groups, active preparations were digested by pepsin although the process was slow and incomplete, ereptic digestion was likewise slow but was fairly complete. On the whole, these data strongly suggest that the active antianemic substance may be an aminohexose polypeptide, however, as the authors point out, no claim to strict chemical individuality can be advanced as yet, since the separation of this type of compound must of necessity be extremely difficult. However, the probable high degree of purity of the preparations employed by these investigators is indicated clinically by the fact that the parenteral administration of only 30 mg gave perceptible reticulocyte responses in suitable patients with pernicious anemia, whereas 80 mg produced maximal responses. The possible relationship of the active hematopoietic substance isolated by these investigators

to products of the partial digestion of gastric mucin, itself a glycoprotein, may be of special interest in view of the well known value of gastric tissue in the treatment of pernicious anemia. Further work along these lines may well yield valuable information.

Current Comment

SAFE PROCESSES FOR HOME CANNERS

An economic emergency, such as that of the last few years, is usually accompanied by increased efforts to conserve food. An important part of the present federal relief program is the urging of the unemployed to raise vegetables and to preserve them by canning. In view of the well known dangers from inadequately processed foods, a careful consideration of safe procedures for the home canning of foods is imperative. The incidence of poisoning from home canned foods, particularly botulism, is most frequent in the case of the "nonacid" foods, such as green beans, carrots, beets, spinach and asparagus, apparently the "acid foods" are more easily sterilized. An examination of much of the literature for the home canner reveals a great confusion in the recommendation for safe procedures. Often the instructions are based on insufficient or incompetent experimental work and as frequently, perhaps, they are biased for commercial reasons. The methods suggested for home canners may be classed into three groups: the boiling water, the oven, and the pressure cooker procedures. A recent critical comparison of these three methods¹ has shown that the pressure cooker process is the only one that is safe beyond question. Standard quart glass jars of cream corn were subjected to the three commonly used methods of food processing, namely, heating in the pressure cooker at 15 pounds, in a hot air oven at 250 F, and in boiling water. The temperature of the contents at the center of the jar was followed by a thermocouple device. The temperature of the sample treated by the pressure method rose rapidly, reaching 212 F in fifty minutes and the maximum temperature of 250 in seventy minutes. The temperature of the boiling water-treated sample rose more slowly and finally reached the temperature of 210 after ninety minutes. The temperature of the oven-treated jar increased even more slowly and at the end of ninety minutes had reached only 188. The importance of careful experiments of this kind cannot be overemphasized. The fact is beautifully demonstrated that at least one and one-half hours of the time employed for processing foods by the boiling water and oven methods is required to bring the temperature of the sample to the temperature of boiling water. Thus, only one to one and one-half hours remains for the destruction of toxic bacteria and their spores. This time is not sufficient, as it has been demonstrated that the spores of some strains of *Clostridium botulinum* are not destroyed in three hours at a temperature of 212. Other experiments similar to that just described have been conducted on other nonacid food with the same

result. These data without question warrant the conclusion that the pressure cooker method of canning nonacid foods is the only safe procedure. This conclusion is in accord with a resolution recently passed by the American Public Health Association that "those who distribute literature on home canning advise the use of the pressure cooker for nonacid foods and that in the preparation of all such literature full consideration be given to bacteriological and chemical knowledge on the art of canning, so that the home maker may be given safe counsel on methods of home canning and may recognize the hazards of home-canned foods inadequately processed in the oven and in boiling water."

Association News

THE KANSAS CITY SESSION

Eighty-Seventh Annual Session to Be Held in May

The American Medical Association will hold its Eighty-Seventh Annual Session in Kansas City, Mo., May 11 to 15, 1936.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

CALIFORNIA

Changes in Health Officers—Dr. Francis P. Wisner, Marysville, has been appointed health officer of Sutter County to succeed Dr. Trusten P. Peery, and Dr. William H. Eaton for many years health officer of Santa Barbara, has been succeeded by Dr. Clarence T. Roome.

Society News—Speakers before the Alameda County Medical Association, June 17, were Drs. Vernon G. Alderson, on "Allergic Asthma," Fletcher B. Taylor, "Gallbladder Therapy," Hobart Rogers, "Significance of Melena," and James Frug, "Cushing's Basophilic Syndromes and Similar Endocrinopathies." All are from Oakland.

Mussel Quarantine Again Established—The state department of public health has established a quarantine on all mussels, covering the coast area from the southern boundary of Monterey County north to the California-Oregon boundary with the exception of San Francisco Bay. Under this ban, the sale or offering for sale of mussels gathered from the specified areas for the period May 15 to September 30 is prohibited.

Dr. Larkey Appointed Director of Welch Medical Library—Dr. Sanford Vincent Larkey, since 1930 librarian and assistant professor of medical history and bibliography, University of California School of Medicine, San Francisco, has been appointed librarian of the Welch Medical Library of Johns Hopkins University, succeeding Dr. Fielding H. Garrison, who died in April. Dr. Larkey is 37 years of age and is a graduate of the University of California School of Medicine. He will take over his new duties in the fall.

GEORGIA

State Society to Award Trophy—The Medical Association of Georgia will award each year a cup to the district of the Georgia Congress of Parents and Teachers adjudged to be the leader in preventive health work in its congressional district for the year. The first presentation of the trophy will take place at the annual meeting of the state medical association in April 1936. The winning district will have its name permanently engraved on the cup and will keep it for a year.

Dr. Kelly Appointed Dean—Dr. George Lombard Kelly, vice dean and professor of anatomy, University of Georgia School of Medicine, Augusta, has been elected dean by the regents of the University System of Georgia, effective September 1. Dr. Kelly has been vice dean since the early part of

¹ Tanner, F. W. Proper Processes for Home Canners. *J. Am. Dietet. A.* 11:18 (May) 1935.

1934 He is 45 years of age, and a graduate of the University of Georgia School of Medicine in 1924 At the annual meeting of the Medical Association of Georgia in 1933 he received the Crawford W Long Medal for original research.

IDAHO

Graduate Instruction at State Meeting—The program of the annual meeting of the Idaho State Medical Association in Boise, September 9-13 has been arranged as a graduate course. Members of the staff of Northwestern University Medical School, Chicago, will present the entire program.

Dr. Lathan A. Crandall Jr. Physiology of the Heart, Response of the Body to Wounds and Infection Recent Advances in Physiology of the Digestive Tract Physiology of the Liver Glands of Internal Secretion

Dr. William H. Holmes Common Forms of Cardiac Disease Pneumonia Medical Management of Peptic Ulcer Recognition and Treatment of the Anemias Practical Management of the Diabetic Patient

Dr. John A. Wolfer Preoperative Preparation of the Patient Wounds Including Burns Surgical Management of Peptic Ulcer Cholecystitis, Significance of Postoperative Symptoms

Dr. William R. Cubbins Fractures of the Femur Compound Fractures Including Osteomyelitis Knee Joint Fractures of the Leg Including the Ankle and Foot Skull Fractures

Dr. George H. Gardner The Gynecologic Patient Pelvic Infections The Unhealthy Cervix, Uterine Bleeding Newer Methods of Diagnosis and Treatment

In addition to this program, lectures will be presented at a meeting for the public.

Dr. Crandall, Behind the Scenes of Medical Science

Dr. Cubbins The Layman's Duty to the Injured

Dr. Holmes Diet and Disease

Dr. Wolfer The Nature of Cancer

Dr. Gardner will deliver a special lecture for women on the subject of menstruation.

ILLINOIS

Personal—Dr. Felix W. Sokolowski, Chicago, has been made managing officer of the Alton State Hospital, succeeding Dr. Dudley T. Dawson, who took a similar position at the Peoria State Hospital.

Units of Diphtheria Antitoxin—The Illinois State Department of Health will in the future issue diphtheria antitoxin for treatment purposes in vials of 20,000 units. When a larger dose is desired, a multiple number of 20,000 unit vials should be obtained. The department officials believe that deaths have occurred in the past because the dosage has been too small. For prophylactic purposes the department will continue to issue 1,000 unit vials of antitoxin.

Chicago

Dr. Hayden Appointed Head of Department—Dr. Daniel B. Hayden, associate clinical professor of laryngology and otology, Rush Medical College, University of Chicago, has been appointed head of the department of laryngology and otology, effective July 1. Dr. Hayden graduated from Georgetown University School of Medicine in 1904, and has been associated with the Rush Medical College for many years.

KANSAS

New Headquarters for County Society—The Sedgwick County Medical Society has purchased a building at 135 North Main Street, Wichita, which it will remodel for headquarters. In addition to the offices of Mr. M. F. Cahal, executive secretary of the society, and his assistants, the building will contain a library and an auditorium for meetings of the society. The second floor will be used for the offices and the first floor will be leased.

Society News—At a recent meeting of the Brown County Medical Society and the woman's auxiliary, Dr. Laurence S. Nelson, Salina, spoke on 'Management of Cases of Fractured Skull,' and Dr. Porter D. Brown, Salina, 'Anesthetics in Labor.'—Speakers before the Cowley County Medical Society in Winfield recently included Dr. Charles C. Hawke, Winfield, on 'Varicose Ulcers and Their Treatment', Dr. Howard L. Snyder, Winfield, president-elect of the Kansas Medical Society, was the guest of honor at the meeting.—The Crawford County Medical Society was addressed May 23, by Dr. Ralph Bowen, Oklahoma City, on 'Practical Management of the Asthmatic Child'.—At a meeting of the Harvey County Medical Society in Newton, June 6, Drs. Andrew W. McAlester, Kansas City, and Abraham C. Eitzen, Hillsboro, discussed infections of the eye and epidemic encephalitis, respectively.—The Labette County Medical Society was addressed in Parsons, May 22 by Drs. Howard E. Marchbanks and Chester Herbert Smith, Pittsburg, on heart diseases and thyroid complications, respectively.—Dr. Vern L. Pauley, Wichita,

addressed the Pratt County Medical Society, May 24, on tuberculosis of the kidney and diseases of the ureter.—At a meeting of the Washington County Medical Society in Washington, June 11, Dr. James Harold Lynch, Fairbury, presented a discussion of diseases amenable to treatment by splenectomy.

MASSACHUSETTS

Memorial Service—A memorial service for the late Dr. George H. Bigelow, director of the Massachusetts General Hospital, Boston, was held in Memorial Church of Harvard University, Cambridge, May 12.

Stimulation of State Hospital Research—Dr. Winfred Overholser, commissioner of mental diseases of Massachusetts has appointed a departmental research committee to stimulate and coordinate research activities in the state hospitals, according to *Science*. Dr. Abraham M. Verson is chairman and other members are Drs. Douglas A. Thom, Roy G. Hoskins, Neil A. Dryton and Harry C. Solomon. The Rockefeller Foundation is supporting research programs in the Worcester and Boston state hospitals as well as a statistical project of the department at Boston, it was announced.

Personal—Dr. Walter B. Cannon, George Higginson professor of physiology, Harvard Medical School, Boston, was elected an honorary member of the National Academy of Medicine of Spain at the recent celebration of the two hundredth anniversary of its founding, *Science* reports.—A portrait of the late Dr. George F. Curley was recently presented to the Milford Hospital by his daughter, Mrs. John W. Gahan, Milford. Dr. Curley was surgeon-in-chief to the hospital until his death in April.—Dr. Douglas A. Thom, Milton, received the honorary degree of master of science in medicine from the University of Vermont at its commencement exercises in Burlington, June 24.—Dr. Paul Dudley White, Boston, delivered the St. Cyres lecture of the National Hospital for Diseases of the Heart, London, July 10 at the house of the Royal Society of Medicine, on 'Congestion Without Myocardial Failure'.—Dr. John H. Nichols has resigned as superintendent of the state infirmary at Tewksbury.—Dr. Richard M. Ash has been appointed health commissioner of Quincy.

MICHIGAN

New Health Unit—The establishment of a new health unit in Calhoun County with Dr. Matthew R. Kinde, Hastings, as director, has been announced. The unit, which is a project of the W. K. Kellogg Foundation is financed in part by appropriations of \$6,000 and \$3,000, respectively, by the county and state. It will open officially September 1. Dr. Kinde has resigned as health director of Barry County to take over the new office. He has been succeeded by Dr. Robert B. Harkness, acting health officer of Eaton County for the past three months.

Society News—Dr. Edgar E. Martmer was chosen president of the Detroit Pediatric Society at the annual meeting, June 19, and Dr. William J. Scott, secretary.—The Lenawee County Medical Society was addressed by Dr. Alpha Rees Klopfenstein, Toledo, June 19, on 'Vesical Neck Obstruction'.—Dr. Vernon L. Hart, Minneapolis, addressed the Houghton County Medical Society, Calumet, July 2, on 'Mechanical and Physiologic Rest in the Treatment of Diseases and Injuries of the Extremities'.—Members of the Jackson County Medical Society and their wives gathered at Clark Lake, June 27, for their annual spring outing.—Dr. Louis J. Hirschman, Detroit, addressed the Muskegon County Medical Society, June 29, on 'Office Management of Common Rectal Diseases'.

MINNESOTA

Personal—Dr. Edward J. Engberg, St. Paul, for many years secretary of the board of medical examiners, was appointed a member of the state board of health by the governor June 24, succeeding the late Dr. Helen H. Hielscher, Mankato. Dr. Max W. Alberts, St. Paul, has succeeded Dr. Engberg on the medical board.

Hospital Association Meeting—The twelfth annual convention of the Minnesota Hospital Association was held at Duluth June 20 and at Lutsen, June 21. Dr. Alloys F. Branton, Willmar, was chosen president-elect of the association and Mr. Victor Anderson, manager, Abbott Hospital, Minneapolis, was installed as president. A. M. Calvin is executive secretary. Speakers at this meeting included

Dr. Bert W. Caldwell, Chicago Hospital Legislation—Federal and State

Dr. Malcolm T. MacEachern, Chicago What Successful Hospitals Are Doing to Overcome Their Difficulties

Mr. Robert Jolly, Houston, Texas, president American Hospital Association What Is the Future of the Voluntary Hospital?

Dr. Lawrence R. Gowan, Duluth The Place of Mental Hygiene in the General Hospital Program

NEW YORK

Medal Awarded by University of Buffalo—The Lucien Howe Medal in Ophthalmology recently awarded to Drs Joseph H Globus and Sidney M Silverstone was conferred by the University of Buffalo and not by the Medical Society of the State of New York, as noted in THE JOURNAL, June 22, page 2274. The award was inadvertently confused with an award with the same name that has been made in previous years by the medical society. The late Dr Howe gave to the University of Buffalo some years ago a sum of money, interest from which was to be used for the manufacture of a specially designed medal to be given annually to the author of a work on an ophthalmologic subject. Dr Harold W Cooper, Buffalo, is chairman of the committee on award.

Society News—Speakers at the third quarterly meeting of the Ontario County Medical Society at Geneva, July 9, were the following members of the Geneva General Hospital staff: Drs Melvin Edgerton Deuel, on 'Indications for Version or Forceps in Occipitoposterior Presentations'; Thomas W Maloney, "Preparation of the Diabetic for Surgical Procedure"; Claude C Lytle, "Abdominal Emergencies"; Robert E Doran Jr, "Resumé of Osteoplastic Cases," and Homer J Knickerbocker, "Preoperative and Postoperative Care."—Dr Frank H Lahay, Boston, addressed the Medical Society of the County of Nassau, May 28, on "Newer Developments in Thyroid and Parathyroid States."—Dr Arthur W Wright, Albany, was elected president of the New York State Association of Public Health Laboratories at the recent annual meeting in Syracuse, Dr Orren D Chapman, Syracuse, vice president, and Miss Mary B Kirkbride, secretary.—Dr Elise S L'Esperance, New York, was elected president of the Women's Medical Society of New York State at the annual meeting in Albany in May. Vice presidents elected are Drs Madge C L McGinness, New York, Alice Stone Woolley, Poughkeepsie, and Edith Fowler Wheeler, Cortland, and the secretary, Dr Marguerite P McCarthy, Solvay.—The medical profession of Rochester gave a testimonial dinner to Dr Floyd Stone Winslow at the University Club, June 20, in honor of his selection as president-elect of the Medical Society of the State of New York. Dr Edward T Wentworth was toastmaster, and speakers included Frank Gannett, publisher of the Gannett newspapers, H Douglas Van Duser, president of the Rochester Bar Association, and Drs Benjamin J Slater, Rochester, and James F Rooney, Albany. About 200 persons were present.

New York City

Hospital Superintendent Appointed.—Dr William B Talbot, assistant director of Grasslands Hospital, Valhalla, since 1928, has been appointed superintendent of New York Post Graduate Medical School and Hospital, to succeed Dr Thomas Dwight Sloan. Dr Talbot was graduated from Tulane University of Louisiana School of Medicine in 1922.

Personal—The physicians and directors of Sydenham Hospital gave a dinner to Dr Max Rosenthal, president of the medical board of the hospital, in honor of his seventieth birthday, May 15, at the Hotel Pierre. Speakers were Mr Simon Bergman, president of the board of directors, Drs Julius Jarcho, Jacob Heiman, Moses H Edelman and Mr David Tishman.—Dr William Bradley Coley will lecture before the Royal College of Surgeons of England, London, October 10, on "Treatment of Inoperable Malignant Tumors with the Toxins of Erysipelas and Bacillus Prodigiosus, Based on a Study of End Results from 1893 to 1935." At that time Dr Coley will be made an honorary fellow of the college.—Dr James W Smith was one of twelve alumni of New York University who received the Alumni Meritorious Service Award at the annual commencement of the university June 12. Dr Smith was graduated from the school in 1917.—Dr Florence Rena Sabin received the honorary degree of doctor of science at the annual commencement of the University of Colorado.

Dr Gasser Appointed Director of Rockefeller Institute—Dr Herbert Spencer Gasser, professor of physiology, Cornell University Medical College, has been appointed director of the Rockefeller Institute for Medical Research to succeed Dr Simon Flexner, who will retire in the autumn. Dr Gasser, a native of Wisconsin, is 47 years old and a graduate of Johns Hopkins University School of Medicine. Previous to his medical training he had taken bachelor's and master's degrees at the University of Wisconsin and had taught physiology there for two years. After graduation from Johns Hopkins Dr Gasser was instructor in pharmacology at Wisconsin for a year and in 1916 went to Washington University School of Medicine, St Louis as instructor in physiology. He served successively as associate and associate professor of pharmacology and in 1921 was appointed professor of pharma-

cology, remaining in that position until 1931, when he went to Cornell as professor of physiology and director of the physiology laboratories. Dr Gasser's chief research interests have been concerned with the coagulation of blood, the problem of traumatic shock and the electrophysiology of nerve.

NORTH CAROLINA

Society News—Dr Lester A Crowell Jr, Lincolnton, addressed the Buncombe County Medical Society, Asheville, June 3, on 'Pneumothorax Treatment of Lobar Pneumonia'.—Drs Edwin P Alyea and Robert A Ross, Durham, were among speakers at a meeting of the Sixth District Medical Society at Burlington, June 20, on "Urologic Back Pain" and "Significance of Gynecologic Pain," respectively.

OHIO

Fund for Library—The late Mrs Jane Moore, Columbus, established by her will a fund for the purchase and maintenance of a medical library in Columbus, in memory of her son, the late Dr Edward Howard Moore. Drs Florus F Lawrence, Hervey W Whitaker and William C Davis, Columbus, are trustees under the will. Medical literature purchased by them will be placed in an alcove in the Columbus Public Library.

Personal—Dr Lyman W Childs announced his retirement as supervisor of health service in Cleveland schools at the end of the school year. He was appointed to the school staff in 1910.—Friends of Dr Milton L Johnston, Harrod, gave a testimonial dinner in honor of his fiftieth anniversary in the practice of medicine, June 12.—Dr Jones L Hurst, Dorset, has been appointed health commissioner of Ashtabula County to succeed the late Dr Walter S Weiss, Jefferson.—Dr Roy C Hunter, Wapakoneta, was recently appointed to the state medical board of Ohio to succeed Dr Fred Wuist, Dayton.—Dr Arthur C Bachmeyer, formerly dean of the University of Cincinnati College of Medicine and now director of clinics at the University of Chicago, received the honorary degree of doctor of science at the commencement of the University of Cincinnati recently.

Society News—Dr Harley O Bratton, Columbus, addressed the Fayette County Medical Society, Washington Courthouse, June 7, on treatment of hypertrophy of the prostate.—Dr Elmer R Arn, Dayton, gave an address on the surgery of malignant growths of the stomach and colon at a meeting of the Warren County Medical Society, Lebanon, June 4.—Dr Benedict Olch, Dayton, spoke on 'The Heart After Forty' before the Greene County Medical Society, Xenia, June 6.—Dr George W Crile, Cleveland, addressed the Marion Academy of Medicine, June 4, on tumors of the breast.—Dr Arnold F Sydow, Cleveland, discussed treatment of burns at a meeting of the Portage County Medical Society, Ravenna, June 6.—Drs Arthur C Ernestine and William J Gardner, Cleveland, discussed "Use of Drugs in Treatment of Heart Disease" and "Surgical Lesions of the Cerebral Blood Vessels," respectively, at a meeting of the Muskingum County Academy of Medicine in Zanesville, June 5.

PENNSYLVANIA

New Health Officers—Dr Eugene H Dickenshied, Allentown, has been appointed medical director of Lehigh County to succeed Dr Jacob Treichler Butz. Dr Victor J Baluta, Shamokin, has been appointed medical director of Northumberland County, succeeding Dr Oscar E Salter, Shamokin. Dr J Glenn Hemington, Uniontown, has been appointed health director of Fayette County.

District Meeting at Williamsport—The Seventh Council District of the Medical Society of the State of Pennsylvania held its annual meeting at Williamsport, July 12. Speakers were Drs Moses Behrend, Philadelphia, president of the state society on 'Differential Diagnosis of Upper Abdominal Lesions as a Factor in Reducing Morbidity and Mortality'; Ruth Hartley Weaver, Philadelphia, "Prenatal and Maternal Care"; Charles C Wolferth, Philadelphia, "Treatment of Heart Disease." Dr Walter F Donaldson, Pittsburgh, secretary of the state society, discussed state society affairs, and Dr William H Mayer, Pittsburgh, social trends and medical service.

Society News—Dr Herbert T Kelly, Philadelphia, addressed the Northampton County Medical Society, Easton, June 21, on 'New Principles and Methods in the Treatment of Diabetes Mellitus'.—Dr Robert H Jeffrey, addressed the Fayette County Medical Society, Uniontown, June 6, on infections of the skin, and Dr George H Robinson, on treatment of hemorrhoids, varicose veins and ulcers of the cervix. The society held its annual picnic jointly with the dentists of the

county at the Umontown Country Club, July 10—Dr Carl E Ervin, Danville, addressed the Cambria County Medical Society, July 11, on "Diagnosis and Management of Chronic Digestive Disturbances"—Dr Hyman A Slesinger, Windber, was host to the Pittsburgh Pediatric Society at a clinic at the Windber Hospital, May 24 Dr Ellwood W Stitzel, Altoona, delivered a paper on "Treatment of Pseudohypertrophic Muscular Dystrophy with Glycocoli"

Philadelphia

Dr Krusen to Head Physical Therapy Department—Dr Frank H Krusen, associate dean of Temple University School of Medicine, has resigned to go to Rochester, Minn., to take charge of a physical therapy department at the Mayo Clinic Dr Krusen has been director of a department of physical medicine at Temple University Hospital since 1931

Faculty Changes at the University—Dr Edward A Schumann, associate professor in obstetrics at the University of Pennsylvania School of Medicine, has been made professor of obstetrics to succeed the late Dr Edmund B Piper Dr James A Babbitt, who has been with the school for many years and was for several years acting head of the department of otolaryngology, has been made emeritus professor of clinical otolaryngology

Personal—Dr Clarence A Patten, associate professor of neurology, University of Pennsylvania Graduate School of Medicine, was recently appointed professor of neurology to succeed the late Dr Theodore H Weisenburg—The Philadelphia College of Pharmacy and Science at its annual commencement, June 5, conferred the honorary degree of doctor of pharmacy on Dr William A Pearson, dean of Hahnemann Medical College.—Dr Martha Tracy, dean of Woman's Medical College of Pennsylvania, has been granted a year's leave of absence from the college Dr Henry D Jump will be acting dean during her absence

Pittsburgh

Changes at the University of Pittsburgh—Dr Stanley S Smith, associate professor of ophthalmology, University of Pittsburgh School of Medicine, has been appointed professor to succeed Dr William W Blair Dr George J Wright has been made professor of neurology to succeed the late Dr Thomas M T McKennan There are sixty-five graduates from the school this year, the incoming freshman class has been reduced from sixty-seven to fifty-five

TENNESSEE

Health at Knoxville—Telegraphic reports to the U S Department of Commerce from eighty-six cities with a total population of 37 million, for the week ended July 6, indicate that the highest mortality rate (20) appears for Knoxville and that the rate for the group of cities as a whole was 10.2 The mortality rate for Knoxville for the corresponding week of 1934 was 17.3 and that for the group of cities, 10.8 The annual rate for the eighty-six cities for the twenty-seven weeks of 1935 was 12.1, as against 12 for the corresponding period of the previous year Caution should be used in the interpretation of weekly figures, as they fluctuate widely The fact that some cities are hospital centers for large areas outside the city limits or that they have large Negro populations may tend to increase the death rates

Society News—Dr Joe T Smith Knoxville, was elected president of the Tennessee Pediatric Society and Dr William W Potter, Knoxville, president of the Tennessee Academy of Ophthalmology and Otolaryngology, at the recent annual meetings —Dr John A McCulloch, Maryville, addressed the Blount County Medical Society, June 27, on "Nonspecific Urethritis"—Memphis physicians presented the program of the Tri-County Medical Association (Carroll, Henry and Weakley counties) at McKenzie, May 14, as follows: Drs Robert Lyle Motley, "Treatment of Circulatory Emergencies," John L McGehee, "Appendicitis During Pregnancy," and Walter A Ruch, "Prenatal Care"—At a meeting of the Dyer, Lake and Crockett Counties Medical Society, Dyersburg, June 5, speakers were Drs Wilson L Williamson and William R. Blue, Memphis, on "Recent Advances in Gynecology and Obstetrics" and "Immunology," respectively—Physicians of Bradley, McMinn, Monroe and Roane counties held a joint meeting at Athens, May 21, with the following speakers, among others: Drs George W Burchfield, Maryville, "Diagnosis and Treatment of Sinus Infections," Robert B Wood, Knoxville, "Pneumothorax as Treatment in Pulmonary Tuberculosis," and William R. Arrants, Athens, "Obstetrics in General Practice."—Dr Jarrell Penn, Knoxville, addressed the Knox County Medical Society, June 4, on "Fractures of the Shaft

of the Femur"—Drs Wilder W Hubbard and Murray B Davis, Nashville, addressed the Lincoln County Medical Society, June 4, on pneumothorax in pulmonary diseases and abdominal pain, respectively

UTAH

Dr Beatty Resigns as Health Officer—Dr Theodore B Beatty, health commissioner of Utah since the state department of health was created in 1899, retired to private life, July 3, and was succeeded by Dr John L Jones, assistant commissioner and state epidemiologist since May 1934 Dr Beatty, who is 72 years old, is a native of Illinois and a graduate of Rush Medical College, Chicago In 1931 Dr Beatty was elected president of the State and Provincial Health Authorities of North America His successor is a native of Utah and graduated from Harvard University Medical School in 1925 Dr Jones received a degree in the Harvard School of Public Health in 1928 and from that year until his appointment in Utah in 1934 was director of the bureau of communicable diseases of the state board of health of Kentucky

VIRGINIA

Group Hospitalization Plan in Richmond—The Richmond Academy of Medicine at a meeting June 11 approved a group hospitalization plan for the city Six hospitals have already approved the plan, according to the *July Virginia Medical Monthly* Commercialism is entirely eliminated, it was said, and every effort will be made under the sponsorship of the academy to make the plan a true community service. For the time being hospitalization will be limited to groups of ten persons, who will constitute not less than 40 per cent of the employed force to which they belong There will be an enrolment fee of \$1 and a monthly fee of 85 cents payable monthly

GENERAL

Diagnostic Manual of Gallbladder Clinic—Physicians who registered at the exhibit of the Gallbladder Clinic of the New York Post-Graduate Medical School and Hospital in the Scientific Exhibit of the American Medical Association at Atlantic City are requested to write directly to the hospital, 303 East Twentieth Street, New York, in order to receive copies of the diagnostic manual The notebook kept at the exhibit containing addresses of interested physicians was lost on the last day of the meeting

Outbreaks of Typhoid—Two women carriers who helped prepare food for a picnic in Philadelphia, May 30, are believed to be responsible for an outbreak of typhoid among the 400 persons who attended Seventy-three cases with five deaths had occurred up to July 6, according to the *Philadelphia Inquirer* Systematic examination of the women who prepared or contributed food for the picnic revealed the carriers, who were not on the city's list of carriers and who had not suspected their condition, it was said—More than 2,500 persons were immunized against typhoid in Richmond County, North Carolina, during June after an outbreak in several towns, newspapers reported, June 22—Private wells in Minneapolis are being examined in an effort to trace the source of an outbreak of typhoid in the city Thirty-five cases with one death had been reported from May 25 to June 27, according to newspaper reports

British Physicians to Visit United States in August—A group of British physicians will arrive in New York on the *S S Georgic*, August 4, on their way to the annual meeting of the British Medical Association in Melbourne, Australia, in September The Medical Society of the State of New York will entertain the visitors on a trip to Grasslands Hospital, Valhalla, Sunday afternoon, August 4, and on the following morning to the Columbia and Cornell medical centers, the New York Academy of Medicine and the Rockefeller Institute for Medical Research There will be an alternative trip to Rockefeller Center and the National Broadcasting Company, the two groups assembling for luncheon at the Waldorf-Astoria The reception committee on behalf of the Medical Society of the State of New York includes Drs Frederic E. Sondern, New York, president of the society, and Arthur J. Bedell, Albany, immediate past president The reception committee for the American Medical Association consists of Dr Morris Fishbein, Chicago, Editor of *THE JOURNAL*, and Drs Austin A. Hayden, Chicago, and Arthur W. Booth, Elmira, N. Y., members of the Board of Trustees Some of the British guests will be accompanied by their wives, making about 100 persons in the group

Medical Bills in Congress—*Change in Status* S 883 has passed the House, directing the retirement of acting assistant surgeons of the United States Navy at the age of 70 years *Bills Introduced* S 3238, introduced by Senator Wheeler,

Montana, proposes to enact a 'Federal Building Workmen's Compensation Act'. The bill provides that every contract entered into with the United States or any executive department, independent establishment, agency or instrumentality thereof for the construction, alteration or repair of any public building or public works shall contain a provision requiring the contractor to provide adequate workmen's compensation insurance for employees on the work who may come within the purview of the workmen's compensation laws of the state in which the work is to be performed. In case of employees not coming within the purview of the workmen's compensation act of the state in which the work is performed, the contractor shall with respect to the injury or death of such employees provide liability insurance pursuant to the Longshoremen's and Harbor Workers' Compensation Act. H. R. 8805, introduced by Representative Sirovich, New York, proposes to enact an act "to prevent the manufacture, shipment, and sale of adulterated or misbranded food, drugs, nonalcoholic and nonintoxicating beverages, and cosmetics and to regulate traffic therein, to prevent the false or fraudulent advertisement of food, drugs, nonalcoholic and nonintoxicating beverages, and cosmetics." H. R. 8835, introduced by Representative McCormack, Massachusetts, proposes to provide for the deductibility, for the purposes of income tax, of charitable and other contributions by corporations.

Pan American Medical Congress—The general scientific assembly of the Pan American Medical Association was held on board the *Queen of Bermuda* en route to the West Indies and Brazil, July 6-11. Among speakers announced in the program were

- Dr. Lewellys F. Barker, Baltimore: Treatment by the General Practitioner of the More Common Diseases of the Nervous System.
- Dr. Morris Fishbein, Chicago: Our Changing Times. A Study of the Significant Advancement in the Nature of Medical Practice and of Current Tendencies in Social Medicine. Also Fads and Quackery in Healing. An Analysis of the Evolution of Charlatanism and an Exposé of Current Tendencies in Quackery.
- Dr. Russell M. Wilder, Rochester, Minn.: Clinical Significance of Recent Discoveries of the Metabolic Function of the Anterior Lobe of the Pituitary.
- Dr. Foster Kennedy, New York: Relationship of Neurology and Psychiatry to General Medicine.
- Dr. Varaxiad H. Kazanjian, Boston: Various Deformities of the Face with Methods of Treatment.
- Dr. Charles C. Dennis, Kansas City, Mo.: Heat in the Treatment of Syphilis.
- Dr. William D. Haggard, Nashville, Tenn.: What Can We Do to Lower the Mortality from Appendicitis?
- Dr. Fred H. Albee, New York: Bone Graft in Repair and Cure of Disease.
- Dr. Joseph Jordan, Ellers, New York: Diagnosis and Treatment of Cancerous Skin Lesions.

Eighteen sections were to hold meetings on shipboard. Other meetings were to be held in Rio Piedras, Puerto Rico, and in Rio de Janeiro and São Paulo, Brazil, with addresses by physicians of the cities visited. Dr. Chevalier Jackson, Philadelphia, is president of the association and Dr. Joseph Jordan, Ellers, New York, director general.

Fraudulent Solicitors—It is reported that a man calling himself "Dr. Al Thompson" and "Dr. A. G. Thomas" has been writing checks on physicians in North Carolina and Virginia. He arranges a visit ostensibly to sell instruments, and on his departure, check books, prescription forms, hospital reports and personal letters are missing. This man is about 40 years of age, 5 feet 8 or 9 inches tall, weighing about 160 pounds. He is red faced and wears heavy glasses and a brown gray suit and hat. A physician from Langhorne, Pa., reports a man calling himself D. A. Thompson and claiming to represent the "Associated Importing Factory 37 West Twenty-Sixth Street, New York," selling desk blotters and felt chair covers. The physician paid him \$6 but the articles were never received. Investigation revealed that there is no such address. From Jasper, Ala., comes the report of a man giving his name as Karter and claiming to be the head of Karter Surgical Service Company of Birmingham. Instruments valued at \$35 were given to the man to be repaired and the work paid for. When the instruments were not returned a visit was made to the address in Birmingham which was found to be a vacant lot. No one in the neighborhood had ever heard of "Karter." This man is described as a dark skinned, smooth shaven person about 5 feet 6 inches tall. He is said to weigh about 130 pounds and to have brown eyes. He claims to have worked for Pfau and Kny-Shearer in New York, is about 30 years of age, knows instruments and tells a plausible story. The St. Louis Medical Society reports that a man who used the name Garrison and introduced himself as a brother of the late Dr. Fielding H. Garrison of the Welch Medical Library, Baltimore, called on the society's librarian. He told of an automobile accident and a fine and asked for a small loan to enable him to get home.

Dr. Frederick Russell Resigns as Director of International Health Division—The resignation of Dr. Frederick F. Russell as director of the International Health Division of the Rockefeller Foundation and the appointment of Dr. Wilbur A. Sawyer, associate director, to succeed him has been announced. Dr. Russell will retire September 1, having reached the age limit. He graduated from Columbia College of Physicians and Surgeons in 1893, and began his career as a member of the Medical Corps, U. S. Army, in 1898, advancing through the various grades to that of colonel in 1917. He resigned in 1920. He was curator of the Army Medical Museum, Washington, D. C., from 1907 to 1913, and also instructor in bacteriology and clinical microscopy at the Army Medical School, where he performed distinguished service in developing and producing the typhoid vaccine which the army has used with great effectiveness since that time. Colonel Russell also devised a culture medium which greatly simplified the identification of the typhoid bacillus. He was professor of pathology and bacteriology at George Washington University School of Medicine from 1909 to 1913 and for the following year lecturer in tropical medicine at the New York Post-Graduate Medical School and Hospital. From 1915 to 1917 Dr. Russell was chief of the board of health laboratory in Ancon, C. Z., and during the World War was in charge of the division of infectious diseases and of the laboratory service of the surgeon general's office, U. S. Army. From 1920 to 1923 he was director of the public health laboratory service of the International Health Board, and since 1923 has been general director of the board. In 1919 he received the Distinguished Service Medal. Recently he was named lecturer on preventive medicine and hygiene and epidemiology at Harvard Medical School, Boston. Dr. Sawyer, a graduate of Harvard Medical School, 1906, has been associated with the International Health Division since 1919, having been associate director since 1927. From 1908 to 1911 he was medical examiner at the University of California, director of the Hygienic Laboratory, 1910-1915, and secretary and executive officer of the California State Department of Health 1915-1918, lecturer in hygiene and preventive medicine, 1914-1916, and clinical professor in the same subject at the University of California Medical School, 1916-1919. He served during the World War and afterward in the surgeon general's office, Washington, D. C., in the control of venereal and communicable diseases. From 1919 to 1922 Dr. Sawyer directed a campaign against hookworm in Australia and was adviser in public health to the Australian ministry of health from 1922 to 1924, assistant regional director for the East, 1923-1924, and director of the public health laboratory service of the international health board, 1924-1927. Dr. Sawyer was also a member of the West African Yellow Fever Commission of the Rockefeller Foundation in 1926 and since 1928 has been in charge of the foundation's Yellow Fever Laboratory in New York.

Government Services

Civil Service Commissions

The U. S. Civil Service Commission announces open competitive examinations for the positions of medical, associate and assistant medical officers, the applications to be on file with the commission not later than July 29. To be eligible, applicants must qualify in at least one of the following optional branches and must state in their applications the branch or branches desired: cardiology, cancer diagnosis and treatment, eye, ear, nose and throat, urology, internal medicine and diagnosis, neuropsychiatry, pathology and bacteriology, roentgenology, surgery (general or orthopedic), tuberculosis, venereal disease (clinical or public health), and general practice (associate grade only). For medical officer, the salary will be \$3,800 a year; for associate medical officer, \$3,200 a year, and assistant medical officer \$2,600 a year. These salaries are subject to a deduction of 3.5 per cent toward a retirement annuity. Further deductions are also provided for depending on the service. Competitors will not be required to report for examination at any place but will be rated on their education and experience on a scale of 100, such rating being based on the sworn statements in their applications and on corroborative evidence. In addition to having certain qualifications persons selected for appointment must pass a physical examination given by a federal medical officer. Application forms may be obtained from any first class postoffice, from the U. S. Civil Service Commission, Washington, D. C., or from the U. S. Civil Service district office in any of the following cities: Atlanta, Boston, Chicago, Cincinnati, Denver, New Orleans, New York, Philadelphia, Seattle, St. Louis, St. Paul, San Francisco, Honolulu, San Juan, P. R., and Balboa Heights, C. Z.

Report of Committee on the Reform of the Curriculum

In the discussions that have gone on for some time in this country among teachers, students and physicians there has been general agreement that the curriculum is overloaded. Students have to spend too much time on subjects of no value to them in their subsequent careers as physicians. The General Medical Council, the body appointed by the government to control medical education and medical examinations, has now expressed its views. A year ago it appointed a committee to consider the information and proposals received by it for the revision of the curriculum. The report of the committee has now been made and the council has ordered that it should be circulated to the licensing bodies and deans of the medical schools. The systems of medical education vary widely in different countries, but there is no evidence that a higher standard of qualification is obtained anywhere else or indeed that other countries are satisfied with their own methods. The committee holds that medical education will be best advanced by developing and improving the existing system. There does not appear to be an appreciable body of criticism of the main principles of the present curriculum, as, for example, its length, the chief subjects required, or the order in which they should be studied. An increase of the present length (five years) would add to the financial burden of medical qualification. The standard of qualification can be improved without lengthening the period by raising the requirements at entry and expending the time available to fuller advantage.

Before admission to the medical curriculum proper an examination has to be passed in general education and in the preliminary scientific subjects. The curriculum proper begins with the study of anatomy and physiology. Registration as a medical student takes place at this point, but not before the age of 17. The committee agrees with the opinion that the medical curriculum proper should not be begun before the age of 18, partly to ensure sufficient general education and partly to await due maturity of mind. The standard of general education should be at least equal to that for the other learned professions and not below that of matriculation for the universities. It should not cease at too early an age and its present level should be raised.

THE PRELIMINARY SCIENTIFIC SUBJECTS

Much of inorganic chemistry has no special educational merit and is not of particular value to the medical student. The omission of such matter would enable organic chemistry also to be taken in the preliminary course and the student at about the age of 18 could pass an examination in chemistry and physics that would satisfy the council and enable him to enter on the medical curriculum proper without further examination in these subjects. Biology is a valuable introduction to the study of anatomy and physiology. It should be permissible for the course to begin, as at present, before registration, but the examination in it should be taken some time after registration and its study should be continued into the subsequent period.

THE MEDICAL CURRICULUM PROPER

The subjects fall into two main groups: the professional scientific, occupying the first two years and the clinical, occupying the final three years. The student should not pass to the second group until he has proved his knowledge of the first by passing an examination. Instruction in applied anatomy and physiology should be continued during the period of clinical studies. There has been considerable criticism of the teaching

of anatomy, that it is taught in too great detail and sometimes by teachers not in touch with its clinical applications, and that it is taught on the assumption that the student is to become a professional anatomist. The committee holds that while these criticisms have some foundation they are less true now than they were some years ago. The committee recommends that the vocational aspects of anatomy be made more prominent by beginning the introduction to the clinical subjects in the second year. Similar criticisms have been made as to the teaching of physiology, but they are less emphatic. It is said that in some schools too much attention is paid to physiology of little vocational value. The committee is not satisfied that this criticism is in general justified. It recommends that physiology and clinical medicine be brought into closer union, especially by continuing physiology into the clinical years and by associating clinical teachers with its teaching. Instruction in the principles of genetics should be given at this stage. Introductory clinical subjects should be taught throughout the second year. These include methods of clinical examination—use of the stethoscope and ophthalmoscope and examination of body fluids—introduction to general pathology and bacteriology, and introduction to pharmacology.

THE PERIOD OF CLINICAL STUDIES

The period of clinical studies occupies the third, fourth and fifth years. Except for reasonable holidays, clinical instruction should be continuous throughout this period and applied anatomy and physiology should be continued by teachers of anatomy and physiology and the clinical teachers jointly. There should be a minimum period of one month's residence in a hospital for medicine and the same for surgery, and two months for obstetrics. Practical instruction should be given in minor operative surgery on the living. A medical clinical clerkship in the hospital wards should be held for six months and a surgical dressership for the same period. Instruction should be given in dietetics, therapeutics and prescribing, physical therapy, principles of nursing, child welfare, psychology and radiology. Throughout the whole period of study attention should be directed to the importance of the measures by which health may be maintained and to the prevention of disease. During the later stages of the period, instruction should be given in the obligations under the national health insurance act and other acts of parliament and in medical ethics.

The Future of the Hospital System

The British Hospitals Association had decided to institute a committee of inquiry into the whole future of the hospital system. The association represents all the voluntary hospitals (hospitals supported by the voluntary subscriptions of the charitable for the benefit of the poor). The altered economic conditions and particularly the immense sum now spent by the state and the local authorities on social services have created new and serious problems for the voluntary hospitals. The rivalry of the rapidly increasing municipal hospitals, supported by public funds, and the need of middle class people for hospital treatment are the main problems. It may be said that the main object of the municipal hospitals is that no citizen shall suffer for lack of hospital treatment. Every one whose illness requires it is entitled to admission, but a graduated charge is made in the case of those who can pay. The London County Council, whose huge municipal hospital system has been previously described in *THE JOURNAL*, has appointed almoners for its hospitals, whose duty will be to interview entrants and assess the contributions they are to make toward the cost of their maintenance and treatment, as has been done in recent years in the voluntary hospitals. With regard to the competition of municipal with voluntary hospitals, an important point is that the former, with public funds behind them, can often acquire better equipment than the latter.

For persons of the middle class, neither of these hospital systems has been designed or are suitable, except that to a limited extent pay wards have been established for the middle class in some voluntary hospitals. The proposal is finding favor that an insurance system be established for them, so that by paying of a graduated amount yearly their families may have the right of treatment in hospitals under the supervision of their own physicians. Their position has been rendered more difficult by the industrial depression and high taxation, while at the same time medical treatment has become more elaborate and therefore more costly. It has been said that only the poor and the rich can get the best medical treatment—the former because it is provided for them in the voluntary hospitals, the latter because they can pay for it.

Effect of the Modified Armbruster Law on Foreign Physicians

Reference has been made in recent letters to student riots and protests made by many medical organizations against the ever increasing number of foreign physicians since the World War. The first attempt to check the influx from other European countries was the passage of the Armbruster law in 1933, which made it obligatory following enactment of the law for every one to be naturalized who desired to secure a state license to practice medicine in France or its colonies. The students who had already matriculated, prior to the passage of the law, were exempted from this requirement. Prior to the Armbruster law, a large number of students from Rumania had been allowed to take the examinations for state license without being obliged to have a French bachelor of arts degree or to pass the examinations of the preliminary medical year (physics, biology and chemistry). The latter exceptions to the standard requirements were the result of a treaty between the two countries dating back to 1860.

Since the passage of the Armbruster law, a larger number of foreigners than ever before applied for state licenses, because those already matriculated in the medical schools were exempt from the obligation of becoming naturalized.

One of the reasons for the influx of foreign medical and dental students during recent years is that the number of such students has been greatly limited not only in other European countries but also in the United States. Other students have been obliged to leave their native countries because of religious or political reasons. Although France has always been very hospitable in its attitude toward foreign students, physicians and dentists, the economic crisis through which the country is passing has caused these professions to feel keenly the competition of such a large number of foreigners.

The original Armbruster law of 1933 thus left too many loopholes, and it became imperative to check the influx of foreign physicians and dentists as well as that of students in these professions.

During the 1934-1935 session of the Paris Medical School, out of a total of 4852 students there were 1530 foreigners—nearly one third. Of these 1,530 foreigners, 689 matriculated as candidates for a state license to practice in France. Of the 1,530, 841 desired only the university diploma which requires the same medical school examinations but does not demand the French bachelor of arts degree before admission to the medical school.

During 1933-1934, 585 state licenses were given by the Paris Medical School to French graduates as compared to 125 state and 112 university diplomas to foreigners. During 1934 and the first six months of 1935, 669 state licenses were given to French and 136 to foreign students. One hundred and twenty-

four university diplomas were granted. The latter constitute simply an honorary degree, often employed by foreign students in securing admission to schools in their own countries.

From 1925 to 1933, 2,376 diplomas were registered in the department of the Seine (in which Paris is situated), central police office. Of these 2,376 licenses to practice, 1,974 were issued to French citizens and 402 to foreigners.

The essential features of the new law as it affects foreigners and as just passed by the legislature are as follows:

In order to practice medicine or dentistry in France or its colonies, a state diploma and naturalization are now obligatory. The only exception to the latter is when those who desire to practice in France are citizens of countries that permit French physicians or dentists to practice without being naturalized. Even under these circumstances a parity must be established between the number of French physicians or dentists in a given country and the number of citizens of such a country who practice medicine or dentistry in France.

Any physician or dentist who has graduated from a foreign school and who wishes to obtain a French state license will be required to pass not only all the examinations of the French bachelor of arts degree but also those of the preliminary medical year (physics, biology, chemistry). Graduates of foreign schools who have complied with these requirements may enter the fourth year of the medical school but will be obliged to pass the examinations of the first three years. The medical school course has been recently lengthened from five to six years.

Foreign students will not be allowed to matriculate in any university unless they possess a French bachelor of arts degree and have passed the examinations of the preliminary medical year in France. No foreign or naturalized students, candidates for a state license, will receive any credit for work done in the medical or dental schools of his or her own country. No foreign student who has failed in examinations or has been refused admission in the medical or dental schools of his or her own country will be allowed to matriculate in a French university.

A special commission must verify every medical or dental diploma within six months after passage of the law. Every foreign physician or dentist who has been naturalized and has been granted a state license to practice shall be compelled to serve the same length of time (usually two years) in the army, navy or air corps as a French physician or dentist. If this requirement has been complied with, permission to begin practice immediately is granted.

If the physician or dentist, possessor of a state license, is exempted by the military authorities from active service, he or she can begin to practice only after an interval corresponding to the duration (two years) of the compulsory military service. This interval becomes double in length if on account of age the naturalized physician or dentist has been absolved on account of having passed the age limit of military service.

No naturalized physician or dentist, even though he has a state license, will be permitted to serve as an expert witness or as a public official until five years has elapsed from the date of graduation.

These requirements of military service do not apply to foreign students now engaged in medical or dental studies until after Dec. 31, 1940 or to foreign physicians or dentists who were practicing in France prior to passage of the law.

In the bill as passed by the chamber of deputies (corresponding to House of Representatives), all physicians and dentists who were not French citizens were compelled to apply for naturalization papers within three months after passage of the law. This paragraph caused much anxiety among American and English physicians and dentists in France, the majority of whom practice in Paris.

A delegation headed by Dr Edmund L. Gros, chief of the medical staff of the American Hospital of Paris, and Dr Edward Orton, Dr Francis J. Wilson and Dr William Davenport Jr, representing the dentists, called on the American ambassador, Jesse I. Straus, and explained to him the serious situation in which they would be placed if this law should be passed as it stands. Some of them have been in France for twenty or thirty years. Many have been volunteers in the French army and helped to organize during the war the American Ambulance Hospital, the American Field Service and other relief organizations.

The American Hospital of Paris, deprived of the American members of its staff would have lost much of its American atmosphere and methods.

As the result of protests by the American and British ambassadors, the senate modified the chamber of deputies bill so as to exclude from compulsory naturalization and subsequent military service all foreign physicians and dentists who had been granted state licenses prior to the passage of the new law. The chamber of deputies at the request of the minister of foreign affairs, Mr Laval, accepted the change made by the senate.

The new law goes into effect immediately and it is hoped that in the near future it will greatly decrease the number of foreign physicians and dentists practicing in France.

Therapeutic Management of the War Injured

The care of the war injured is a task of the federal government which is delegated to a special department of the federal ministry of labor. This department provides for the needs of the war injured now living and also for the necessities of the dependents of the two million who lost their lives in the World War. A pension is not granted unless the reduction of the earning capacity caused by the war injury amounts to more than 25 per cent. As the number of the war injured who are drawing a pension is about 800,000 (THE JOURNAL, Dec 1, 1934, p 1721) it may be estimated that the total number of war injured ranges around 1,500,000.

Under the federal law pertaining to the aid to be given the war injured, only such persons can claim therapeutic care as can furnish evidence of having developed a *versorgungsleiden* by which is meant all disturbances of health resulting from an injury suffered in the war service. The duty of deciding whether the disturbance of health is due to a service injury devolves on the pension board. In practice, certain distinctions with reference to the results of service injuries have come to be accepted. For example, a disturbance of health may have originated as a result of a service injury or it may merely have become exacerbated. Examples of the former are wounds and infectious diseases. In addition there are disturbances of health in which there is no causal but only a temporal connection with the war service. In such cases aid is likewise granted, although there is no legal claim for aid. Furthermore, a distinction is made between direct and indirect results of war injuries. A direct result, for example, would be a stiff knee-joint following a gunshot injury. An indirect result would be a flatfoot developing following the loss of the other leg.

Wherein the therapeutic care consists is exactly specified in the law. It comprises medical treatment supplying with medicines and other remedies that may be needed to insure the success of the therapeutic aid or to alleviate the effects of the service injury. In addition, a course of treatment, including maintenance in a sanatorium may be granted, or, if other forms of treatment do not yield adequate results, treatment in a spa may be approved. Blinded persons are given a dog specially

trained to guide the blind. In some instances the *krankenassen* with their comprehensive organization are called on to aid in the application of therapeutic care, but the reich has retained in its own hands a portion of the therapeutic care, since some of the forms of aid it is necessary to grant the war injured go beyond the customary performances of the *krankenassen*. Most of the war injured are insured in the *krankenassen* but even though that is not the case the reich may make use of the *krankenassen* in rendering aid to the war injured. The *krankenassen* do not, however, aid in giving courses of treatment in spas and sanatoriums. These forms of treatment are used chiefly in service injury disorders in which one anticipates especially favorable effects from the specific virtues of the waters of certain health resorts, more particularly, stubborn neuralgias associated with loss of limbs, chronic inflammations of joints, rheumatic disorders, diseases of metabolism, certain forms and grades of tuberculosis of all organs, and disturbances of circulation. For the application of such forms of treatment the reich provides a number of special institutions, which are directed by medical officers. As a rule, the length of spa treatment is limited to four weeks, and sanatorium treatment for lung patients to from three to six months, but in exceptional cases the time may be extended. In addition for the clinical observation and treatment of severely tuberculous, infirm and chronically ill war-injured there are four such federal institutions for patients whose condition is not amenable to domiciliary treatment. According to statements made in Munich by one of these medical officers, in 1932 6,161 patients were allowed treatment in spas or health resorts and 1,781 in sanatoriums.

Orthopedic aid is also administered without the mediation of the *krankenassen*, by means of special orthopedic welfare centers. In 1921 orthopedic aid was granted to 23,892 persons with one amputated arm, to 191 persons with both arms amputated, to 53,869 with one leg amputated, to 1,084 with both legs amputated, to 3,803 persons who wear supporting apparatus, to 91,614 persons required to wear orthopedic shoes, and to 1,635 persons in need of wheel chairs or other form of vehicular aid. The range of usefulness of the orthopedic centers has remained unchanged. There are today thirty-two such centers, which, as of Oct 1, 1933 had given aid to 236,642 war injured. No more recent statistics have been issued. The number of prostheses, their purchase, repair and length of wear, and their price range are governed by special provisions. In 1932 the following prostheses were furnished: 1,600 new artificial arms, 9,000 artificial legs, 60,000 pairs of orthopedic shoes, 600 wheel chairs and other vehicular aid, 2,650 rain coats, and 183,000 small orthopedic aids. In addition, 146,000 pieces of apparatus were repaired. The total sum expended was 9,000,000 marks (\$3,600,000).

Abortion and Race Hygiene

The attitude of the German medical profession toward abortion is now unequivocally established on the basis of principles that have been set up by the government (THE JOURNAL, January 26, p 331). While the discussions on the fundamental question may be regarded as closed, some important matters of detail have sprung up. It is surprising to learn from an article that appeared in the *Deutsches Aerzteblatt* the official organ of the medical federations, that a half million abortions still occur annually in Germany. From the effects of abortion, at least 80,000 women have died either at once or within five years from hemorrhages, septic disorders, or the like, which amounts to 16,000 a year. In addition 300,000 women are said to have become ill because of the intervention, half to two thirds of whom fail to recover their health. Most of these abortions are carried out by underhanded quacks. A recent court decision has brought the question of abortion into an interesting connection with the eugenic principles of the national socialist state. Strictly speaking, the eugenic indications for

abortion are absolutely rejected in Germany. However, not long ago the Hamburg eugenics court, on which devolves the task of enforcing the German sterilization law, declared that the interruption of pregnancy for eugenic reasons is exempt from punishment, assigning as the reason for such decision that a "racial emergency" exists. The court decided in one case in which the child would in all probability present hereditary defects for the interruption of pregnancy, in order that sterilization might be performed at once. Many jurists have condemned the decision of the Hamburg court on the ground that it exceeded the limitations imposed on judges. The court, nevertheless, has not yielded from its point of view, and, in the meantime, during the course of the year 1934, approved twenty-nine interruptions of pregnancy for eugenic reasons. It has even taken the unusual stand that a pregnancy can be interrupted without a court order in case either parent has been legally declared to present hereditary and transmissible defects. The Hamburg eugenics court, in justification of its decision has declared that, for the sake of the continued existence and health of the German people, an unborn child that is likely to present hereditary and transmissible defects may be destroyed, even though thereby the legal regulations concerning abortion are violated.

Other eugenics courts, however, do not endorse the standpoint of the Hamburg court. For instance, the eugenics court of Berlin decided, with reference to a minor child with hereditary epilepsy, to postpone sterilization until six months after completion of the existing pregnancy. These questions are now being eagerly discussed in the special medical journals bearing on these problems.

Reforms in Sex Education

Dr W. Gross, the director of the Rassenpolitisches Amt of the national-socialist party, has emphasized the need of considering sex education of the youth. He referred particularly to statements that Dr. Ockel had made in the official *Deutsches Ärzteblatt*. Dr. Ockel calls attention to the unfortunate conditions that have resulted from the fact that almost nothing has been done to solve this difficult problem. At present the number of illegitimate births shows a rapid increase. The present trend of developments is shown clearly by statistical data recently published by Dr. Harmsen, who supervises in Berlin a home for unmarried mothers among the educated classes. According to his annual report for 1933, of 206 mothers twenty-two belonged to the 14-20 age group. Most of these came to the home during the last third of the year 1933 in constantly increasing numbers, nor did the beginning of the year 1934 show any decrease, but rather the contrary. These mothers come frequently from very respectable families. In many cases it is uncertain which one of two or more comrades is the father of the child, so that "we have a state of affairs that we have seldom, if ever, observed during our period of activity." There appears to be no intention on the part of these young persons to establish a more permanent union or to enter into marriage relations.

It is not surprising that most urgent appeals for help have been heard. Physicians and teachers especially, have been asked to cooperate. Parents must be induced to give their children early instruction in sex matters. A series of lectures should be given that would furnish them the basis for such instruction. The first instruction in sex matters should be given children between the ages of 5 and 10 years and is primarily the duty of the parents. First instruction should consist of a simple presentation of the essential facts of procreation, propagation and birth. In the second stage of instruction from the eleventh year up to puberty, the emphasis may be placed on the fact of procreation together with gradual enlightenment on the internal processes, in which the school and the home may work together toward a solution of the task. In the third stage,

more detailed knowledge of sexual processes may be given, this being a problem of guidance of juveniles. These urgent appeals and the statistics cited reveal all too clearly what unpleasant conditions have developed in recent years, as the result, in part, of the lack of systematic instruction in sex matters.

VIENNA

June 3, 1935

Celebration of the Sesquicentennial of the Vienna General Hospital

The celebration of the sesquicentennial of the founding of the Vienna General Hospital during the last two weeks of May, was closely intertwined with the fifty-fifth International Postgraduate Course, and the Vienna and Austrian medical societies took the occasion to hold, during these two weeks, special sessions with unusually interesting programs, participated in by eminent scientists, including some from foreign countries.

The history of the General Hospital was presented in an address by Professor Neuberger. The festivities were held on a magnificent scale, under the auspices of the central government, the municipal authorities and the Vienna faculty of medicine. Twenty-six different nations were represented. The sesquicentennial celebration should have been held last year, since the General Hospital was opened Aug. 16, 1784, but the political disturbances of last summer made it seem advisable to postpone the celebration. Emperor Joseph II, who was known in history as the first liberal ruler, founded the General Hospital because he was deeply interested in public health work and in medical instruction. Where the General Hospital now stands, there stood at that time the so-called Gross-Armen-Haus, with seven large inner courts. This institution was altered and several additions were made, after the pattern of the institution in Leyden (Netherlands), to adapt it for the uses of a hospital. The new institution, which came to be known as the General Hospital, obtained as an annex a "medizinisch-praktische Lehrschule für Aerzte." At the request of the head of this "clinic," any patient in the hospital that was needed for instruction purposes was placed at his disposal. It was not until 1795, under the leadership of Professor Vetter, that a dissecting room was equipped. The "Leichenhaus" then established still bears in gold letters the motto "Indagandis sedibus et causis morborum" (for research of the sites and causes of diseases) and is still functioning with full force. Dr. Vetter laid the foundation for the magnificent collection of anatomopathologic specimens, which is now the pride of the institution. In 1801, the first vaccination against smallpox ever applied in Germany was performed in the Vienna General Hospital. The essential nature of typhoid was studied here for the first time. Among the important acquisitions that originated in the General Hospital were the development of obstetrics by Boer in 1810, in which he emphasized that birth is a physiologic and not a pathologic process, the first ophthalmologic clinic in central Europe, under Professor Beer (1812). The Vienna Medical School reached a high stage of development under Rokitansky as pathologic anatomist and Skoda as internist and diagnostician, around 1840. In the surgical clinic, Schuh performed in 1847 the first major operation under ether anesthesia. In 1848 Hebra became director of the dermatologic clinic. Semmelweis demonstrated that puerperal sepsis is an infection and showed how it could be prevented. In 1860 Türck made systematic examinations with a laryngoscope devised by Garcia and thus became the founder of laryngology, in 1868 experimental pathology was introduced by Stricker. Through Billroth, Vienna became the Mecca of surgeons (1867-1894). He resected the esophagus, extirpated the larynx and

performed suprapubic prostatectomy and pylorus resection—operations previously unknown in Europe. Urology and cystoscopy, and likewise catheterization of the ureters, were practiced by Dittel in Vienna for the first time, orthopedics was advanced by Albert and Lorenz. The field of hypnosis and psychology was opened up by Krafft-Ebing, and psychoanalysis was discovered and developed by Freud. Cocaine as an anesthetic was introduced in 1884 by the ophthalmologist Dr. Koller (now in America). Otology was advanced by Politzer, rhinolaryngology by Hajek, and roentgenology by Holzknecht. Three men connected with the General Hospital have won the Nobel prize: Wagner-Jauregg, Barany, and Landsteiner. In the past three decades, the General Hospital has become too small for the needs of modern times. Six clinics have been moved to the new hospital, and thus sufficient space was secured for the clinics remaining in the old building. These have been completely modernized without disturbing the external appearance of the institution.

In connection with the celebration, an extensive exhibit, which gave a complete survey of the modern methods of treating and caring for patients, was organized. In the Museum of Natural History an exhibit was opened by the minister of public health, containing all the plans and presentations that affect the century and a half of history of the General Hospital, also old instruments, trephined skulls from prehistoric epochs, antique prescriptions and drugs, and, among other things, the first microscope, the first stethoscope, the first laryngoscope and the first ophthalmoscope.

Various societies held meetings simultaneously with the festivities. In the Verein für Psychiatrie und Neurologie, Professor Marburg and Dr. Suva discussed cavity formation in the spine following trauma. Dr. Scheinker presented a paper on observations on the spirochete in multiple sclerosis. Dr. Stengel discussed acute encephalitis.

At the special session of the Society of Internal Medicine, Professor Eppinger spoke on the pathology of inflammation. Professor Wenckebach delivered a long address on "Respiration and Circulation." Anemia and its dependence on the activity of the liver and the stomach was presented by Professor Hitzengerber. Anemia as the cause of dermatologic manifestations was considered by Professor Arzt. Professor Falta spoke on diabetes, and Professor Bauer on icterus and its nonoperative treatment; the latter discussed also hormones.

At the meeting of the Oesterreichische Krebsgesellschaft, Professor Fraenkel delivered the memorial address on "The Problem of Cancer." He said that cancer must not be conceived of as a local disorder but as a manifestation conditioned by the constitution of the patient, and that chronic irritants, which are often regarded as the cause of the carcinoma, have only a modest role. It is now possible, in a large percentage of cases, to establish the diagnosis in an early stage by means of serologic tests. Many other scientific societies held sessions during the festivities commemorating the founding of the General Hospital. At the closing session of the Gesellschaft der Aerzte, Professor Clairmont of Zurich spoke on the "Development of the Surgical School of Vienna During the Past Hundred and Fifty Years." He emphasized the invigorating effects on medicine that are traceable to this center of research. Every day of the two weeks was filled with entertainment: receptions instituted by the government and by the mayor of the city, unveiling of a monument to the first director of the hospital, inspection of exhibits and of hospitals in Vienna and vicinity, special performances in the theaters, and social events in honor of foreign guests.

Statistics on Marriages and Offspring

The recent edition of the Statistical Compendium of the Republic of Austria and the City of Vienna contains statistics that are of interest to physicians. Striking an average for ten

years, it appears that only 0.1 per cent of the men entering matrimony are under 20 years of age, while only 0.1 per cent of the women are under 16. Six per cent of the brides are under 20. Only 8 per cent of the bridegrooms are under 25, although 25 per cent of the brides are under that age. The maximum of the men (more than 50 per cent) married between 25 and 30. Forty per cent of the women belong to this age group when they marry, which is also the maximum. Sixty-five per cent of the brides belonged to the 20-30 age group, while the same percentage of the bridegrooms belonged to the 25-35 age group. Of the men 1.5 per cent belonged to the 50-60 age group, while 0.4 per cent were past 60 when they went to the altar. On the other hand, only 0.5 per cent of the women belonged to the 50-60 age group, 0.2 per cent to the 60-70 age group, and less than 0.1 per cent to the group whose age was above 70. It is evident, therefore, that there is usually a difference of five years in the ages of the bridegroom and the bride. During the past fifteen years, to be sure, the average age of bridal couples has been somewhat higher, as the statistics for 1932 show, but the difference of five years in their respective ages has remained the same.

Further tables deal with the relative age of the parents and their children. It is shown that 5 per cent of all living legitimate children were the offspring of mothers who were more than 40 years old, and that 1.5 per cent of the fathers were more than 50 years old. Most children (about 35 per cent of all births) are born from three to ten years after the marriage of their parents, although 0.5 per cent of the children are born after their parents have been married twenty years or more. In the rural sections of the country, bridal couples are generally older than in the cities, and the age of the bride particularly is from one to two years greater than in the cities. In more recent years, however, the young people are marrying earlier. A drop in the birth rate is observable in most parts of the country. In Vienna, for example, the decline amounts to 50 per cent as against 1924, although in the provinces it is only from 15 to 22 per cent. The decline in the number of illegitimate births is only from 4 to 5 per cent, so that, in comparison with the legitimate births, they show an increase.

Prof. Dr. Benjamin Gomperz

Prof. Dr. Benjamin Gomperz, formerly a well known otologist and a favorite pupil of Professor Politzer, has died. Gomperz devoted himself especially to otology pertaining to young children. His textbook was translated into practically all cultural languages, and his otologic department in the Kinderkrankeninstitut in Vienna, in which he served for forty years, was the mecca of the physicians specializing in this branch. He published works also on anatomy and physiology of the organs of audition, on the testing of hearing in children, on the constitution in hardness of hearing, and on problems of heredity.

Prof. Dr. Emil Mattauschek

With the recent sudden death of Prof. Dr. Emil Mattauschek, a great man has passed on. He had attained the age of 66, forty years of which he had spent as a physician and director of the psychiatric-neurologic department of the General Hospital. He devoted himself even in his younger years to scientific research and to organization, and served, during the war, as head of the medical department of the army. Later he became the chief psychiatrist of the army. He was the collaborator of the Nobel prize winner Wagner-Jauregg in connection with the latter's researches on malaria therapy in dementia paralytica and was well known by reason of his own research on the anatomy of the central nervous system. He was also a well known court psychiatrist, his textbook being still widely used.

ITALY

Defense Against Gas Attacks

Major Ferri delivered recently, before the *Sindacato Medici di Roma e Provincia*, a lecture on the means of defense against gas attacks. He said that the first mask of modern type in which granules of a solid substance were relied on to give protection against gas attacks, was devised in 1915 by Professor Guareschi. This model did not come into use, and the Italian army employed masks of layers of gauze impregnated with neutralizing solutions until in January 1918 the Guareschi idea was used in the form of the English respirator. The mask, which is essentially a filtration apparatus, still occupies first place among the means of individual defense. Various types of masks have been designed for the army and for the civilian population. They do not differ so much from the standpoint of quality or the capacity to resist a concentrated attack as they do from the point of view of duration of protection and the cost of manufacture.

The speaker pointed out the important things to be considered in a mask: its efficacy with reference to the concentrations of gas likely to be encountered in the field, its tight fitting qualities, and the degree of comfort with which it can be worn.

The wearing of a mask reduces the physical and mental powers of the wearer, but suitable breathing will notably reduce the discomfort of its use. The use of this principal means of individual defense may be regarded with satisfaction.

In some types of chemical warfare, Major Ferri pointed out that it is necessary to use hermetically sealed apparatus that absolutely isolates the wearer from his environment, supplies him with the necessary oxygen, and absorbs the carbon dioxide of the expired air. Such apparatus may be one of two types, either with an oxygen reserve or a mechanism for the production of oxygen. The apparatus with a production system is based on sodium peroxide or on so-called solid oxygen which releases compressed oxygen, pure or mixed with carbon dioxide. At present, protectors supplying compressed oxygen are preferable. The short period of effectiveness, averaging about an hour, the cumbersomeness and weight, the difficulty of handling, the cost, and other disadvantages prevent, for the present the supplying of such protectors to the whole army. It may however, be feasible to supply this apparatus to certain branches of the artillery, the corps of engineers and the sanitary service.

The need of protecting the entire surface of the body against the action of vesicant gases (dichlorodiethylsulphide and dichlorobeta-chloro-vinylarsine) requires the use of special garments. These are made of an impermeable fabric treated in a special manner and consist of a hood, gloves and boots. The eyes and the respiratory passages are protected by the mask. These garments cause disturbances in the circulation and in the respiration. In summer the body temperature rises above normal, particularly in persons performing physical labor. A temperature of 38 C (100.4 F) is often reached and a hyperthermia up to 39.2 C (102.5 F) has been observed. Attempts have been made to improve the qualities of these garments but without much success. Their use should be confined to specialists, and they should be used only for short periods.

The author spoke then of the organization of a collective defense against gas attacks, the composition of the air, the temperature, and the degree of humidity. In order not to exceed from 15 to 2 per cent of carbon dioxide or 17 per cent of oxygen it is sufficient to provide 1 cubic meter of air per hour for each person. These amounts may be made available in hermetically sealed retreats or in retreats with filtered air. In many cases the hermetically sealed retreat will be sufficient, with or without regeneration of the air. The problems in providing a collective defense are complex, and practical economic

questions must be taken into consideration. The physician has to insist to get his demands respected, for the civilian population has grown weary of using the gas mask—the fundamental means of gas defense.

Aid for Tuberculous Students

The directive council of the *Federazione nazionale per la lotta contro la tubercolosi* discussed recently plans for rendering therapeutic and prophylactic aid to students of the higher institutions of learning. In accordance with existing laws, these provisions appertain to the *Opera universitaria*, which, for the attainment of such ends, pays half of the premiums for the insurance of all students against tuberculosis and by means of its own sanitary bureau provides gratuitously for the periodic examination of the students. At the time of their matriculation and also at the beginning of each school year, all the students are subjected to a medical examination, the results of which are recorded in an individual health record book, which is brought down to date by the sanitary bureau of the *Opera universitaria*. Some of the more important morphologic and objective observations are recorded, such as the essential anthropometric measurements and the results of the radiologic examination of the respiratory apparatus. The record book is returned to the student on completion of his studies.

Students who are found to be affected with tuberculous disease and who are no longer insurable in an insurance organization may receive gratuitously ambulatory treatment either at the *Opera universitaria* or at the clinics. The director of the local *Clinica medica*, who presides also over the sanitary bureau, participates in the management of the *Opera universitaria*.

JAPAN

(From Our Regular Correspondent)

May 29, 1935

The Effect of Storage on Rice

The rice control law that has been presented to the imperial diet created a great sensation. As rice is the staple food of the Japanese, the price has to be regulated by the government by controlling the quantity on the markets. The average crop of rice is about 300 000 000 bushels, and the surplus rice is going to be stored, under the new law. The sixteen warehouses for this purpose managed by the government have a limited capacity, which naturally causes from time to time disposal of the rice to provide for the new. Now comes the question of the nutritive value of old rice that has been one or two years in the warehouse. About this important matter there are two opinions: one holding that there is no difference and the other insisting that there is a great difference between the new and the old rice. The rice bureau of the agricultural and forestry department says that experiments with the old and the new unhulled rice made in feeding lovebirds show a great difference. The old unhulled rice caused symptoms of beriberi when the birds were fed only this rice, while they soon recovered their health when they began to be fed with the new rice. This fact shows that the vitamin content of the rice decreases as it grows old. Rice that is kept more than a year usually never sprouts and does not have so sweet and delicious a flavor as new rice. The price, therefore, is about one third that for new rice. On the other hand Dr. Kagawa of Tokyo Imperial University opposes the opinion of the decrease in vitamin B and asserts that there is no difference between old and new rice if it is kept with the embryo bud about it. His experiments on pigeons have been elaborate. Professor Shimazono says that wormy and wet rice loses its embryo bud, which is essential for nourishment. Whether old and new rice are the same or not depends mostly on the method of storing it.

Dr. Fujimaki of the nutrition bureau of the hygienic laboratory of Tokyo says that the rice harvested in the fall begins to

have its vitamin destroyed in the rainy season of the next year (June), 20 or 30 per cent and sometimes 60 per cent of the vitamin is destroyed by then. If rice is kept more than three years the vitamin will be entirely destroyed, he says. Dr Akutsu, an expert in the commissary department of the army, reports that the vitamin of rice is generally destroyed at the rate of about half every year. In the army it is made a rule to eat up the rice between one rainy season and the next, for the rainy season causes a great change in various respects.

All this shows that there must be some difference in old and new rice, especially when it cannot be stored under ideal conditions. Mr Nakamura, an expert of the agricultural office, says that even if the vitamin B of rice decreases as the days pass, the vitamin requirement can be easily supplied by other subsidiary articles of diet and produce no harm to the human body. The government is reported to be in a dilemma whether to adopt this new control law or not, from both the political and the health point of view, but many believe that the law will sooner or later be passed.

A Survey of the Blind

According to official report, the number of the blind throughout the country was 76,260 in 1932, or 11.67 persons per 10,000 of population, including about the same number of men and of women. The Central Association for the Relief of the Blind, having been granted a government appropriation, has begun the treatment of the blind, free of charge as far as possible. In Tokyo in April, ophthalmologists examined 622 patients, of whom 114 cases would recover their visual power if properly treated, while 355 cases were hopeless. The medical college hospital of Tokyo Imperial University reexamined 264 and announced that fifty-five will surely recover their sight and that for 195 there is some hope. Treatment is now being given 255 patients in hospitals free of charge. The real cause remains obscure why so many blind persons have not yet been examined thoroughly in Tokyo. Perhaps it is due to the ignorance or bad economic condition of the sufferers. The association will continue the work next year in much wider areas.

The Number of Physicians

According to the home office, the number of physicians registered in April was 76,516. The number of newly registered medical men was 3,294 in 1934. The registration fees amounted to 65,880 yen, each one paying 20 yen. The number of practitioners is 49,844, or 7.41 per 10,000 population. There should be an increase of about 3,000 physicians every year in the future.

Personals

Prof Kaname Komuro, ex-president of Nagasaki Medical University, died April 18, aged 55. He was an authority on otorhinolaryngology. He resigned the presidency of the university and remained a professor. He was a man of lofty character.

Dr Teisuke Komoto of Nagoya Medical University was appointed professor at Nagasaki Medical University and he is to be president before long. After his assumption of office, the university is expected to have a new chair of tropical diseases. As more than 100 medical students from the South Sea Islands have come to Japan recently, this university intends to send its graduates to the south hereafter.

Prof T. Maeda of the Tokyo Imperial University, who is to attend the international surgical conference to be held in Cairo, is earnestly planning to have the next conference, in 1941, held in Japan. The year 1940 will be the 2,600th year of the foundation of the empire, and he wants to have at least one international medical conference here.

Prof Dr K. Mizoguchi has been appointed president of the Kyushu Medical College, succeeding Dr Takayama, new president of Nagasaki Medical University.

Marriages

WILLIAM NICHOLAS FORTESCUE, Boston, to Miss Lottie Markham Hundley of Durham, N. C., June 5.

WILLIAM K. PURKS to Miss Mary Helen Kemper, both of Vicksburg, Miss., June 22.

ROBERT J. BOGAN to Miss Evelyn Frances Summers, both of Memphis, Tenn., June 1.

ROLLAND H. PRIEN to Miss Mary A. Frassetto, both of Gilroy, Calif., June 3.

FRED H. KRAMORIS to Miss Sylvia Heese, both of Milwaukee, June 1.

Deaths

Charles Andrew Fife, Philadelphia, University of Pennsylvania Department of Medicine, Philadelphia, 1897, formerly associate professor of pediatrics, University of Pennsylvania Graduate School of Medicine, member and past president of the American Pediatric Society, served during the World War, aged 63, chairman of medical administration committee of the Babies' Hospital of Philadelphia, on the consulting staff of St. Christopher's Hospital and Frankford Hospital, Philadelphia, and the Burlington County Hospital, Mount Holly, N. J., chief of the medical service of the Children's Hospital of the Mary J. Drexel Home, on the staff of the Presbyterian Hospital, where he died, June 15.

George Thomas Moseley, Buffalo, New York Homeopathic Medical College, 1885, College of Physicians and Surgeons, Medical Department of Columbia College, New York 1886, fellow of the American College of Surgeons, at various times on the staff of the Gowanda State Homeopathic Hospital, Helmut, Erie County Hospital and the Millard Fillmore Hospital, Buffalo, J. N. Adam Memorial Hospital, Perryburg, and the Batavia (N. Y.) Hospital, aged 70, died, June 22, of myocarditis and arteriosclerosis.

Sidney J. Burleson, San Angelo, Texas, Maryland Medical College, Baltimore, 1905, past president of the Tom Green-Coke-Crockett-Concho-Irion-Sterling-Sutton Schleicher Counties Medical Society, formerly secretary of the McCulloch County Medical Society, medical director of the Western Reserve Life Insurance Company, on the staff of the Shannon West Texas Memorial Hospital, aged 60, died, April 5, in a local hospital, of perforated gastric ulcer.

Howard Barton Bryer, West Warwick, R. I., University of Maryland School of Medicine, Baltimore, 1909, formerly member of the state legislature, health officer and school physician, member of the examining board of the county during the World War, on the courtesy staff of the Rhode Island Hospital, Providence, aged 54, died, May 23, of cirrhosis of the liver.

Philip Densmore Amadon, Monroe, Mich., University of Michigan Medical School, Ann Arbor, 1926, fellow of the American College of Surgeons, formerly instructor of surgery at his alma mater, on the staff of the Mercy Hospital, aged 35, died, June 9, in the University Hospital, Ann Arbor, of pneumonia.

William H. Longmire, Elizabethton, Tenn., Lincoln Memorial University Medical Department, Knoxville, 1914, member of the Tennessee State Medical Association, aged 44, died, May 16, in the Veterans' Administration Facility, Johnson City, of hypertensive heart disease and coronary occlusion.

Connell Edward Murrin, Scranton, Pa., Jefferson Medical College of Philadelphia, 1904, member of the Medical Society of the State of Pennsylvania, served during the World War, on the staffs of the West Side Hospital and St. Mary's Keller Memorial Hospital, aged 60, died, June 5.

Joseph Thomas Herrick, Springfield, Mass., University of the City of New York Medical Department, 1883, member of the Massachusetts Medical Society, veteran of the Spanish American War, formerly on the staff of the Springfield Hospital, aged 75, died, June 2, of chronic nephritis.

Herbert William Ellam, Gardner, Mass., Harvard University Medical School, Boston, 1904, fellow of the American College of Surgeons, served during the World War, for many years on the staff of the Henry Heywood Memorial Hospital, aged 55, died, June 4, in Melrose Highlands.

Ephraim George Gray, Ludington, Mich., University of Michigan Department of Medicine and Surgery, Ann Arbor, 1905, member of the Michigan State Medical Society, on the

staff of the Paulina Sterns Hospital, aged 56 died, June 6, of cerebral hemorrhage and diabetes mellitus

William Russell Garland ♂ Plymouth, N H, Dartmouth Medical School, Hanover, 1886, member of the Associated Anesthetists of the United States and Canada, president and medical director of the Emily Balch and Soldiers and Sailors Memorial Hospital, aged 70, died, June 5

Alonzo Russell Jarman ♂ White Hall, Ill, Chicago Medical School, 1922 past president and secretary of the Greene County Medical Society, proprietor of the White Hall Hospital, aged 41 died, June 26 in the Palmer Sanatorium, Springfield, of pleurisy with effusion

Walter Cox ♂ Irvine, Ky, University of Louisville Medical Department, 1912, secretary of the Estill County Medical Society served during the World War aged 46 died, June 6, in the Good Samaritan Hospital, Lexington, of pneumonia and military tuberculosis

Frank Burr Marshall ♂ Muskegon, Mich Kentucky School of Medicine, Louisville, 1896 past president of the Muskegon County Medical Society, on the staffs of the Mercy and Hackley hospitals, aged 63, died suddenly, May 30 of angina pectoris

Gustav Adolf Mausert, Los Gatos, Calif, Hessische Ludwigs-Universität Medizinische Fakultät, Giessen Hesse, Germany, 1899, formerly adjunct clinical professor of otology, Long Island College Hospital, Brooklyn, aged 62 died, June 1, of nephritis

William A Anderson, Glencoe, Ala, Memphis (Tenn) Hospital Medical College 1906, member of the Medical Association of the State of Alabama, aged 55, died, May 26, in a hospital at Tuscaloosa, of hypostatic pneumonia and arteriosclerosis

William Emile Cramer, Kansas City Mo, Hahnemann Medical College and Hospital, Chicago, 1888, Kansas City (Mo) Hahnemann Medical College, 1906, aged 70, died May 31, in the Wesley Hospital of perforation of the gall-bladder

David Emanuel P Reed, Russellville Ind Kentucky School of Medicine, Louisville 1898, member of the Indiana State Medical Association, served during the World War aged 62, died, May 31, of cerebral hemorrhage

Wallace Ainger Armour, Kansas City, Mo Kansas City Medical College, 1895, member of the Missouri State Medical Association, formerly member of the board of education, aged 67 died, June 14 of cerebral hemorrhage

J Stuart Wallingford, Paris, Ky Medical College of Ohio, Cincinnati, 1895, member of the Kentucky State Medical Association, on the staff of the W W Massie Memorial Hospital aged 66, died, May 31, of angina pectoris

Horace O Sparks, Piedmont, Ala, Atlanta College of Physicians and Surgeons, 1902, member of the Medical Association of the State of Alabama aged 54, died, May 15, in Birmingham, of chronic nephritis and uremia

Ernest Eugene Fankhauser, New Martinsville W Va Baltimore Medical College, 1902, member of the West Virginia State Medical Association, formerly member of the town council, aged 61, died, May 31, of arteriosclerosis

John Milton Stevens, Hyde Park Vt University of Vermont College of Medicine Burlington 1897 member of the Vermont State Medical Society, aged 62 died June 17 in the Copley Hospital, Morrisville, of pneumonia

Frank Gillingham Morrill ♂ Peoria Ill Northwestern University Medical School, Chicago 1908, served during the World War, on the staff of St Francis Hospital aged 54, died, June 9, of coronary thrombosis

Harry Malcolm O'Brien, Cleveland, St Louis University School of Medicine, 1918, served during the World War aged 45 died, May 15 in the Charity Hospital of pneumonia and tuberculous anal fistulas

Richard Elmer Shurtz, Buhl, Idaho Rush Medical College Chicago, 1897, served during the World War aged 64, died, May 21, in the Twin Falls (Idaho) County General Hospital, of heart disease

Clyde Leigh Appleby, Peabody Kan Kansas Medical College Medical Department of Washburn College, Topeka 1907, aged 56 died, May 29 in Wichita, of erysipelas and bronchopneumonia

William Calvin Brice, York S C, Medical College of the State of South Carolina Charleston 1926 member of the South Carolina Medical Association aged 35 died June 11, of heart disease

John Henry Walling, Vinemont, Ala (licensed in Alabama in 1889) aged 85, died, April 15, of chronic nephritis

John Paul Emerson, Pittsburgh, University of Pittsburgh School of Medicine 1935, aged 24, died May 25

Harry L Coffman, Los Angeles, Medico Chirurgical College of Philadelphia, 1901, aged 68, died, April 30

Bureau of Investigation

DIABETICINE

Another Fraudulent "Diabetes Cure" Debarred from the Mails

William Lee Thomas and Arthur S. Huyck have been engaged in the sale through the mails of a product fraudulently represented as a cure for diabetes, known as "Diabeticine." The two men did business under the trade name, first, "Illinois Diabeticine Company" and later "Artlee Remedy Company."

Investigation seems to show that Diabeticine is, apparently, nothing more than chopped-up wild carrot (popularly known as Queen Anne's lace). This puts the preparation in the class of ninety-nine out of every hundred quack "diabetes cures," namely, that of a diuretic. Practically every fake cure for diabetes has an irritating effect on the kidneys so that by producing a greater excretion of urine, the amount of sugar in any given specimen will naturally be decreased, although the total sugar output may actually be increased. This fact and the further fact that every swindle of this kind calls for a rigid, although not a scientific diet, explain the passing enthusiasm that sufferers from diabetes sometimes exhibit for

The exploiters of this pernicious nostrum, doubtless knowing full well that their stuff would not eliminate sugar from the urine, stated that "the occasional presence of sugar in the urine should not be misconstrued as inefficiency on the part of Diabeticine," because, according to the concern, the preparation "drives the excess sugar from the blood stream through the kidneys and out with the urine."

Diabeticine was analyzed both chemically and microscopically by the government experts. In addition, biological tests were made of the preparation in the Pharmacological Laboratory of the United States Department of Agriculture. Mr. Crowley reports in his memorandum that these tests proved that the preparation would not "purge the blood of its excess sugar" nor would it "drive the excess sugar from the blood stream through the kidneys." They found, also, that, contrary to the claims of the Diabeticine concern, the preparation would not revive or stimulate the islands of Langerhans of the pancreas to increased action.

Expert medical testimony in the case regarding the claims and representations made for Diabeticine was to the effect that the preparation would not afford any relief whatsoever, either immediately or gradually, in the treatment of diabetes. The only benefit to be expected from the treatment would be that which resulted from the diet prescribed, which benefit would be the same whether taken with or without Diabeticine.

Although the advertising and printed matter put out by Thomas and Huyck under the name of the Illinois Diabeticine Company gave the impression that they were specialists in the treatment of diabetes, the facts were that neither man had any medical training or was competent to pass on medical questions and are reported to have admitted to the Post Office inspectors who investigated the case that they did not even know the ingredients of Diabeticine, which was being sold by them.

Testimonials, as is always the case in the exploitation of "patent medicine" frauds, were used in the exploitation of Diabeticine. One of the most glowing of the testimonials published purported to come from one W. L. Thomas. This is William Lee Thomas, one of the exploiters of this fraud. At the time the matter was investigated, the postal authorities report that they interviewed Thomas' physician, who stated that Thomas was at that time suffering from diabetes!

Solicitor Crowley's memorandum to the Postmaster General closes with these words: "A reading of all the literature in this case would lead the average person to believe that the preparation will, in fact, cure persons suffering from diabetes, whereas, according to the medical evidence before me, the preparation is wholly worthless in the treatment of that disease and may cause users to lose their lives as a result of their failure to adhere to the proper treatment and diet. The evidence before me shows, and I so find, that this is a scheme for obtaining money through the mails by means of false and fraudulent pretenses, representations and promises. I therefore recommend that a fraud order be issued against the names set forth in the caption of this memorandum."

Postmaster General James A. Farley on June 18, 1935, issued a fraud order against the Illinois Diabeticine Company, the Artlee Remedy Company, and their officers and agents as such. The order forbids the Postmaster at Chicago, Ill., to pay any postal money order drawn to the order of the Diabeticine outfit, and directs the local Postmaster to inform the remitters of such postal money orders that payment has been forbidden, and to return all letters and other mail matter directed to the Illinois Diabeticine Company, etc., to the senders, with the word "Fraudulent" written or stamped on the outside of such letters.

Principles of Practice—The art of medicine is to observe, to correlate those observations, and to reason logically to conclusions that must finally become the true principles of practice. Those were the qualities that made Thomas great. His greatness lay in the principles upon which his practice was founded. It was upon right principles that he insisted, not upon this or that mechanical appliance.—Ridlon, John. *Personal Remembrances of Hugh Owen Thomas*, *J. Bone & Joint Surg.* 17: 506 (April) 1935.

products of this class. Incidentally, the Diabeticine fraud is not the only quack remedy for diabetes in which wild carrot appears. There was put out, first from Buffalo, N. Y., and later from Detroit, Mich., a nostrum "Mellitine," which also seems to have had Queen Anne's lace for its essential ingredient. While Diabeticine was said to be "derived from plants which, combined, have a highly therapeutic value in the treatment of diabetes mellitus," Mellitine was said to be "derived from certain plants which have a highly therapeutic value in the treatment of diabetes mellitus."

On May 4, 1935, the Illinois Diabeticine Company and the Artlee Remedy Company were furnished with a copy of a memorandum of charges on file in the office of the Solicitor of the Post Office Department, calling upon these concerns to show cause on June 6 why a fraud order should not be issued. No one appeared in behalf of either concern on the date set for the hearing. The Hon. Karl A. Crowley, Solicitor of the Post Office Department, in a memorandum to the Postmaster General, sets forth the essential facts found by the postal authorities in their investigation of this fraud. According to the Diabeticine advertising, the product was said to be "derived from a plant which has a highly therapeutic value in the treatment of diabetes mellitus." It was set forth that "Diabeticine purges the blood of its excess sugar" and had, it was alleged, a "tonic action upon the pancreas" which, it was said, "arrests the disease." The Diabeticine Company further stated that it was firmly convinced that insulin "actually contributes indirectly to the further progress of the disease."

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address but these will be omitted, on request.

JAUNDICE AND INTESTINAL PARESIS AFTER APPENDECTOMY

To the Editor—A patient operated on for acute appendicitis developed jaundice and abdominal distention on the second postoperative day. It is now the seventh postoperative day and the distention continues. There is little if any peristalsis. Peritonitis is questionable. He is restless and mildly delirious. Duodenal drainage and venoclysis were instituted from the start. What good or harm if any might come from the use of atropine or strychnine with especial regard to the effect on intestinal paresis? It is my understanding that atropine paralyzes the vagus endings and would be contraindicated when one is trying to maintain or stimulate peristalsis; also my impression of strychnine is that it acts only on the spinal centers and exerts no tonic effect on the autonomic sympathetic nervous system. What is your opinion as to the wisdom of morphine when there is no pain and paralytic ileus threatens? Does scopolamine added to morphine usually act as a better cerebral sedative in toxic delirium than the morphine alone? What is your opinion about bromides, chloral paraldehyde and phenobarbital as better mental sedatives than morphine in toxic delirium? Please do not publish my name.

M D Texas

ANSWER.—Following operation for appendicitis, jaundice may be due to phlebitis, infection through the portal vein, the systemic circulation or the lymphatics, with metastatic abscesses in the liver.

Extension along the lymphatics may rarely produce liver abscess formation directly but it may cause obstruction of the common duct because of enlarged glands compressing the common duct, with jaundice, and perhaps be followed by infection extending up the biliary system.

Jaundice may result from a pyemia or septicemia as a toxic or infectious hepatitis.

A local peritonitis or phlebitis in the region of the infected appendix may be the source of any of the foregoing conditions.

The peritoneum may be able to care for a moderate amount of infection but, in the event of local abscess formation, surgical drainage is indicated.

The symptoms described of a paralytic ileus with or without a local peritonitis call for fluids and duodenal drainage.

Atropine is contraindicated, while certain drugs may be of value.

Physostigmine stimulates peristalsis. Experimental work has shown that in combination with solution of pituitary the results are better than with either drug alone. Some surgeons consider solution of pituitary dangerous because of its rapid action while others use strychnine with physostigmine to stimulate peristalsis.

Strychnine increases the tone in both plain and striped muscles but alone is of little value in intestinal distention. Ephedrine is reported to be of value in paralytic ileus and is also of value in maintaining the blood pressure following operation.

Morphine quite definitely increases intestinal tone and segmental peristalsis but delays propulsive peristalsis in the colon. Morphine is indicated both in the prevention and in the treatment of paralytic ileus, as it maintains the tone in the muscle and tends to prevent the serious effects of dilatation. It is given for this beneficial effect in the absence of pain. Hypertonic sodium chloride solution either intravenously or as a retention enema is of great value in paralytic ileus. Morphine usually allays a toxic delirium but may occasionally increase it.

Scopolamine depresses the terminations of the same nerves as atropine but it differs in depressing both the cerebrum and the respiratory and vasomotor centers in the medulla. On account of the pronounced susceptibility of certain persons to the action of scopolamine, it should be given cautiously. Owing to the depressing action on the respiratory center morphine and scopolamine should be limited to small doses, although they act well when given together either as a cerebral sedative or for pain. However, large doses of scopolamine and occasionally morphine may actually increase restlessness and are contraindicated in severe toxemia.

In the absence of pain, for which morphine is the best sedative, other drugs are often better either alone or combined with it for toxic delirium.

The bromides depress the central nervous system and in mild excitement or nervousness are decidedly helpful, but feeble compared to morphine, chloral hydrate, paraldehyde or the barbitol group.

Chloral hydrate has no analgesic action. It may weaken the heart, lower the blood pressure and depress the respiratory centers. It should be given cautiously, and in toxic conditions it is usually avoided.

Paraldehyde resembles chloral hydrate in its action on the nervous system but is not so depressing to the heart. It is ordinarily considered a reasonably safe sedative in a toxic delirium.

Phenobarbital is of value in certain stages of mild delirium, but if large doses are required it may produce an uncontrolled physical restlessness. It is not free from danger, especially in low blood pressure or in persons with arteriosclerosis, and, like other drugs, it should be chosen only when the organs of its elimination are not badly damaged.

In severe toxemia, any drug should be given with great caution.

PHOSGENE AND OTHER POISON GASES

To the Editor—The Query and Minor Note on Phosgene Poisoning (THE JOURNAL July 13 p 140) gives an excellent description of the characteristic symptoms, signs and pathologic changes produced after a prolonged exposure to an atmosphere known to be saturated with a heavy concentration of phosgene. However it does not discuss the following possibility, about which I should like to be informed. Suppose that a person has been exposed for some time to a contaminated atmosphere of unknown chemical composition and death occurs from one to three days later presenting the characteristic symptoms, signs and pathologic changes stated in the note. Can it be said with reasonable certainty that the atmosphere to which the person had been exposed contained a dangerous concentration of phosgene or are there any other gases that will produce the same effect? Please omit name.

Ph D New York

ANSWER.—There are many other gases that could produce essentially the same type of pathologic effect as phosgene gas. Among these might be mentioned chlorine, chloropicrin, chloromethyl, chloroformate, trichloromethyl and phenyl carbamate-chloride, or combinations of these. As a result, unless it was definitely known that phosgene gas was present, it would be extremely difficult to say which of these gases, if present, was responsible, all have their effect on the alveoli and small bronchi of the lungs, which would be followed by lung edema. There are, however, a few clinical signs at the beginning that might be useful in determining the nature of the gas. With chlorine gas the concentration would have to be much stronger, the effect on the eyes and upper respiratory tract would be more marked, and the appearance of the edema would be somewhat delayed.

Chloropicrin, like chlorine, would cause a more pronounced effect on the eyes and the upper respiratory passages. It would also cause greater sensory irritation to the upper respiratory passages, and the pain in the chest would be more pronounced and there would probably be attacks of vomiting.

EFFECTS OF HUMIDITY

To the Editor—Can you give me any information or refer me to any literature with regard to the effect of high humidity on workers in industrial plants? In a local textile mill an attempt has been made to raise the humidity in certain processes from 55 to 65 per cent the temperature remaining at from 72 to 75 F. The employees complain bitterly of the increase claiming that acute nose and throat infections are much more common at 65 per cent and many more than usual have complained of muscular pains in various locations. Any information you can give me on this subject will be appreciated.

ARTHUR L KINNE M D Holyoke Mass

ANSWER.—Just what the optimum range of humidity is is a matter of conjecture. There seems to exist a general opinion, supported by some experimental and statistical data, that warm, dry air is less pleasant than air of a moderate humidity, and that it dries up the mucous membranes in such a way as to increase susceptibility to colds and other respiratory disorders.

For the premature infant, a high relative humidity of about 65 per cent is demonstrably beneficial to health and growth, and according to Huntington this seems to be the case for adults also. All of these studies indicate that the optimum humidity must always be considered in combination with temperature.

Until more exact information is secured, it would be desirable to restrict the comfort zones to the range of relative humidity employed in the comfort zone experiments, namely, 30 to 70 per cent. Relative humidities below 30 per cent may prove satisfactory from the standpoint of comfort, so long as extremely low humidities are avoided. From the standpoint of health, however, the consensus seems to favor a relative humidity between 40 and 60 per cent.

Dry air produces an excessive loss of moisture from the skin and respiratory tract. Owing to the cooling effect of evaporation, higher temperatures are necessary, and this condition leads to discomfort and lassitude. Moist air, on the other

hand, interferes with the normal evaporation of moisture from the skin and, again, may cause a feeling of oppression and lassitude, especially when the temperature is also high."

"In the comfort zone experiments of the A S H V E Research Laboratory, the relative humidity was varied between the limits of 30 and 70 per cent approximately, but the most comfortable range has not been determined. In similar experiments at the Harvard School of Public Health, a relative humidity of 70 per cent was found to be somewhat humid in winter by about half of the subjects who were stripped to the waist, even when the dry bulb temperature was 70 F or less. In summer a relative humidity of 30 per cent was pronounced a little too dry by about a third of the subjects wearing warm weather clothing. So long as the temperature was kept within proper limits, the majority of the subjects were unable to detect sensations of humidity (i e., too high, too low, or medium) when the relative humidity was between 30 and 60 per cent. This is in accord with studies by Howell, Miura and others."

In quoting this material from the 1935 "Guide" of the American Society of Heating and Ventilating Engineers, it is the intent to record the impression that humidity from 55 to 65 per cent is unlikely to promote nose and throat infection and instead that such conditions are much more likely to arise when humidities are low and temperature correspondingly high. Furthermore in this situation involving humidities and temperatures a third most important factor in comfort is air motion. Given even a moderate amount of movement of the air, a relative humidity near 60 per cent at 72 F may not be regarded as direful.

CONFECTIONERS ITCH OR BAKERS DERMATITIS

To the Editor—A young woman who works in a bakery handling and selling bread and cakes came to me with a skin condition on her fingers. Two fingers on each hand had round raised flat vesicles about 1 cm in diameter the borders of which appeared indurated and reddened. The vesicles dried in about twenty four hours leaving a raw chapped and fissured skin, which itched. Is ringworm infection a likely diagnosis? Could this infection have come from the bread? Would this infection be more likely to involve skin with small unhealed cuts? How could the diagnosis have been made definite? Please omit name.

M D New York

ANSWER.—Since early times bakers, pastry cooks and confectioners have been held to be liable to a wide variety of skin disorders. Modern research seems to show that "bakers eczema" is caused not by any ordinary ingredient of the bread but by one of the so called flour improvers usually ammonium persulphate, sometimes calcium acid phosphate. In regard to the former, Australian reports show that in "allergic" persons as little as one part in a hundred thousand may cause an eczema. In regard to the latter, Prosser White found confectioners' self-rising flour very irritating in patch tests and attributed this to the presence of acid calcium phosphate, from 4½ to 6 pounds in 280 pounds.

Deliquescent compounds, such as salt and sugar, are unduly active when in crystals, dehydrating the tissues they touch. Packers of sweets as well as makers frequently have skin lesions on the hands. The French have written much on the subject of the "mal des confiseurs," the typical form of which is onychia, affecting chiefly the middle and ring fingers, but there are also cases of bullae and pustules without onychia. White gives a case of dermatitis from handling cinnamon-sugar, in which the cinnamon was found to be the causative agent.

Most writers accept the term 'confectioners' itch' or dermatitis or psoriasis, but White holds that a distinction must be made between skin lesions that are merely incidental to certain occupations and those which are actually due to the occupation. An eczema can be called occupational with certainty only

if at least one of the ingredients handled gives a positive result with the patch test.

These conditions are described by

ANXIETY NEUROSIS

To the Editor—A white woman aged 36 shows symptoms of nervousness is easily tired and has a sensation of choking or a tight feeling in the neck. She has occasional heavy and dull headaches which previously were more severe with pain starting in the supra-orbital region and radiating to the occiput. There is a slight burning sensation of the eyelids. The condition was slightly relieved by refitting of glasses eight months ago. There is no exact dizzy feeling but sudden sinking sensations occur. Slight roaring sensations in the ear are aggravated by the slightest excitement. She has a slight head cold with soreness in the region of the posterior portion of the turbinates. The teeth are poorly repaired but there are no root infections. Tonsillectomy was done in 1933. There is a continuous sensation of phlegm in the throat but the patient is unable to cough it up. There is a sensation of tightness and choking in the throat especially when the arms are raised over the head also a sensation of tightness on swallowing. No coughing occurs except a slight hacking in an attempt to clear the throat of the sensation of phlegm. Tenderness is noted on pressure on the chest in the region of the third and fourth left ribs 4 inches from the midsternum. No hemoptysis has been observed. Shortness of breath occurs on exertion and palpitation on excitement and exercise. The pulse is regular. There is no pain in the left axilla and arms. The appetite is poor but the patient must eat three times a day or the stomach feels upset. There is no flatulence or belching of gas. The bowels are regular twice daily. There is generalized pain round the umbilicus. A sensation of deep pain occurs in the midabdomen when the patient stoops; this condition is aided slightly by the wearing of a tight abdominal girdle. The urinary system is normal. Menstruation started at the age of 12 and is regular every twenty six days. There have been four normal pregnancies the last one occurring a year ago. For the last three years the patient states, one month menstruation has been normal and on alternate months it has appeared abnormal. At these times she says a heavy sensation of general ill feeling has been accompanied by swelling of the legs (varicose veins). In other words the varicose veins are aggravated every alternate month. The patient is more nervous and the condition of the throat is aggravated. This month she complains of a bearing down sensation of the pelvic organs. This condition has been present at various other times. Sensations of itching of the skin have occurred at various times without apparent cause. There are no pathologic changes in the head. The thyroid is slightly enlarged (small simple goiter?). Examination of the chest and lungs gives negative results. There is slight pain on pressure over the cardiac area. There is a slight tricuspid murmur. The pulse rate is 78. Blood pressure is 128 systolic 74 diastolic. The blood vessels are soft. There is definite tenderness in the region of the right costal margin or in the gallbladder area probably caused by chronic cholecystitis. Pain is elicited on palpation of McBurney's point and also in the corresponding area in the left abdominal quadrant. Bimanual examination reveals backward displacement of the uterus with a first degree prolapse. Definite tenderness of the appendix is elicited. The right ovary is normal the left ovary is slightly cystic. There are marked varicosities in both legs. Please give me from this meager history your opinion as to the cause of the choking sinking sensations. I am satisfied that the patient has a chronic infection of the gallbladder and appendix as well as a misplaced uterus and cystic ovary but can her complaints be due to these ailments? A basal metabolism test was made two years ago and was said to be normal. Please state also your suggestions as to treatment.

M D, Wisconsin.

ANSWER.—When one hears the story of such a multiplicity of more or less unrelated symptoms, one immediately suspects a functional rather than an organic disturbance. In such situations, painstaking diagnostic methods should be employed before an organic disturbance is definitely decided on particularly when surgical intervention is associated.

In this case the definite departures from the normal consist of pelvic disturbances, a retrodisplacement with prolapse and a cystic ovary, varicose veins, and a slight thyroid hypertrophy without change in the basal metabolism. It is difficult to attribute the symptoms in this case to these sources.

On the other hand, all the subjective symptoms described fit into the picture of an anxiety neurosis or an effort syndrome.

The dizziness choking and sinking sensations are commonly found in functional disorders. The fact that some of these symptoms are aggravated at the menstrual period is additional evidence of the functional basis.

Abdominal tenderness in the region of the colon is frequently encountered in the vagotonic and sympathicotonic types. This colon tenderness is often indistinguishable from tenderness of the appendix or gallbladder and the differential diagnosis must be based on symptoms other than the tenderness.

The alternating character of the menses has been observed. This has been attributed to ovulation from alternate ovaries with a different corpus luteum response from each ovary.

Thus, in this case the "normal periods" are the result of ovulation from one ovary, while the "abnormal periods" are the result of ovulation from the other.

Any suggestions for treatment must assume that a definite diagnosis has been made, as the treatment must be wholly guided by the cause of the symptoms. With this picture, however, great care must be used to make sure that surgical intervention offers a fair hope of improvement. It has been found that such treatment, when it fails, usually leaves the patient worse than before.

GLANDULAR DISTURBANCE WITH ALTERED METABOLISM

To the Editor—A woman aged 39 years height 5 feet 4 inches (163 cm) weight 220 pounds (100 kg) a brunette well educated exceptionally brilliant and an efficient housewife has two brilliant children aged 10 and 5 years. Both births were normal. No miscarriages have occurred and no menstrual disturbances. The patient's appendix was removed in 1915. The tonsils were removed in 1922. Abdominal adhesions were operated on in 1931. Infected upper teeth were removed in 1933. The gallbladder was removed in March 1934. There had been no other sickness or operations. The patient states that she is in an extreme state of fatigue most of the time. She says that she just does not have the power to do the things she wishes to accomplish and that it is necessary for her to limit her movements and rest each day. If she exceeds a certain pace she soon finds herself exhausted. She also states that she has pain around her heart. This pain is more or less severe and at times extends to the left shoulder arm and forearm. These signs have been rather constant for a period of two or three years and have grown worse especially since the gallbladder was removed. The pains come on at intervals and appear to be a part of the fatigue signs. Their severity varies. She states that when this pain is over her heart the heart labors and feels as if about to stop. Respiration is not much affected. However she perspires or her skin becomes moist. Examination shows the patient many pounds overweight. Her general physical condition is good except that she has a blood pressure far below normal: systolic 92 diastolic 64. The heart rate is 68. These readings are made from repeated studies over a period of time. The heart is normal in position and outline the valves are intact it is functioning normally. Rhythm is poor. There is an extrasystole. The force of the heart contractions is poor. I have seen the patient in these heart attacks. The pain is rather severe. The heart rate is slow and the force of contraction weak. Beats miss about every seventh one. Heat over the heart area gives relief. I have never given an opiate in this case. Glyceryl trinitrate and other heart stimulants do not appear to make any change. After these attacks the patient relaxes and falls asleep and after a few hours awakes in good condition. The diagnosis made early was gallbladder disease probably gallstones with anxiety neurosis (moderate). I assured the patient when the gallbladder was removed that I anticipated the heart signs and fatigue would clear up. Now that these have remained and are gradually growing worse I am asking suggestions. Are low blood pressures found in neurosis of any degree? Or am I dealing with a mild coronary condition or a fatty degeneration of the heart? Please suggest any further study I might make in the case to arrive at a better diagnosis also treatment, if any. Please omit name. M D New Hampshire

ANSWER—The picture described in this question has all the marks of a glandular disturbance resulting in a disordered metabolism. In such a complicated affair the disturbance usually involves more than one gland.

There are a number of additional observations that might aid in arriving at a conclusion. It is important to know whether the overweight condition has always existed or whether it appeared suddenly following pregnancy or following acute infection or some other factor that may have disturbed a previously normal glandular metabolism.

The fat distribution might furnish some clue to the disturbing element, as would also the presence or absence of myxedema.

A determination of the basal metabolic rate is of primary importance.

The question states that there is no menstrual disturbance but it does not state the character of the menstruation or whether it has been in any way altered.

A hypothyroidism is suggested by the overweight by the fatigue, and by the relatively slow pulse. This condition is usually associated, however, with a diminution of mental acuity and a diminution of the menstrual flow. Other signs of hypothyroidism not dealt with in the question are cold intolerance and a dry skin and hair.

A disturbance of pituitary function would account for the overweight but this condition is not usually associated with excessive fatigue and with a normal menstrual function.

A diminished adrenal cortical function would account for the fatigue and low blood pressure but not for the overweight. A combination of factors must be considered.

The cardiac pain is doubtless due to a deficient coronary circulation but it seems unlikely that this is on an organic basis or that any marked coronary disease exists, nor does it seem likely that fatty degeneration of the heart exists. Fatty

degeneration of the heart, except as an immediate sequel to severe acute infection is almost unknown as a pathologic entity, and fatty infiltration of the pericardium tends to increase the cardiac circulation rather than diminish it.

It is quite possible to have coronary pain as a result of low blood pressure. The possibility of an anemia that may contribute to the deficient coronary circulation is not determined by the question.

The carbohydrate metabolism may also play a part in the fatigue and pain in this case. Blood sugar determinations during the attack might prove helpful. An improper mobilization of sugar will result in a relative hypoglycemia, and fatigue or pain may ensue. The diet in this case is not dealt with and it is possible that the carbohydrate intake is too greatly restricted.

It is quite possible that an anxiety neurosis may be present. An anxiety neurosis frequently causes fatigue, pain and low blood pressure, but it will not cause the overweight and it is almost invariably attended by an elevation of the pulse rate. It seems unlikely that it will produce the whole picture in this case.

SO CALLED ATROPHY OF BRAIN

To the Editor—A patient of mine recently returned from a Chicago hospital where a diagnosis of primary atrophy of the brain frontal lobe was made and instructed that there was nothing to be done for her. The patient complains of severe headaches which are almost constant but vary in severity. It has been necessary to use morphine in half grain doses to obtain the slightest relief. Is there anything in the recent literature to throw light on this condition? Please omit name. M D, Michigan

ANSWER—Primary atrophy of the frontal lobe of the brain is not a clinical entity. Pathologically it is possible to get an atrophy of the frontal lobe in cerebral vascular disease, dementia paralytica, Huntington's chorea, cerebral neoplasm and Pick's disease. The latter is known also as hereditary cerebral degeneration. It was described for the first time in American literature by Hoedemaker and Matthews (*Arch Neurol & Psychiat* 28 1449 [Dec.] 1932). It is suggested that a careful neurologic examination be made with lateral stereoscopic and anteroposterior views of the skull. The optic fundi and visual fields should be examined. When all these data are assembled, one can give an impression as to the possible diagnosis. For the severe headache one may give 100 cc. of 50 per cent dextrose intravenously or 6 ounces of 25 per cent magnesium sulphate solution in a pint of lukewarm water as a retention enema. Morphine should not be used under any circumstances, because of its medullary effect. If a neoplasm is present, decompression or removal of the tumor should be done.

SIMULTANEOUS INOCULATION AGAINST DIPHTHERIA AND SMALLPOX

To the Editor—I was asked to immunize against diphtheria 113 and vaccinate against smallpox 96 children of school and preschool age. I should appreciate it if you would be kind enough to let me know the following: 1 In immunization of children against diphtheria is it better procedure to test first all children 10 years of age or older with the Schick test? (For immunization I am going to use alum precipitated toxoid.) 2 Is it possible to administer alum precipitated diphtheria toxoid and vaccination against smallpox on the same day? (According to Dr W T Harrison on account of the tendency of virus to localize at the site of precipitated toxoid injection smallpox vaccination should not be done until the nodule following toxoid injection has disappeared.)

D V OGIEVSKY M D Klickitat Wash

ANSWER—1 It is desirable to Schick test children 10 years of age and older in order to determine who are susceptible and need immunization.

2 If no emergency exists it probably would be best at this time not to immunize against diphtheria and smallpox simultaneously.

SMALLPOX VACCINATION

To the Editor—A child less than a year old has been unsuccessfully vaccinated three times. There is no question concerning the potency of the vaccine used or the method of vaccination. There is no possibility of acquired immunity but the question does arise concerning natural immunity. How many unsuccessful vaccinations should be made before it is safe to assume that natural immunity exists? Please omit name.

M D Indiana

ANSWER—According to Heman Spalding late chief medical inspector of the board of health of Chicago, "all who have not had smallpox are susceptible to vaccinia at least once. To this rule there is probably no exception. In an extensive experience I have never met with one. The operation should

be repeated until a successful result is obtained. To say a person is 'insusceptible to vaccinia' because several trials are negative is unjustifiable. I have known several to lose their lives because physicians had given this false information" (Pediatrics, by various authors, edited by Isaac A. Abt 6 169, 1925). It appears as if a child may be temporarily insusceptible to vaccination. Sometimes many attempts at vaccination must be made before a typical take is secured. Spalding wrote that he had known eight, ten and in one case thirteen attempts at vaccination before success was obtained. There is no good ground for believing that failure of primary vaccination means immunity in the absence of a previous attack of smallpox.

USE OF CONVALESCENT SERUM—TRANSFER OF ALLERGY

To the Editor—I have been unable to find satisfactory information dealing with the following questions: 1. Is there any danger in giving human convalescent serum at repeated intervals say a month? 2. Is there any likelihood of transmitting allergic states in this manner? 3. Would it be more painful if the serum in small doses was given subcutaneously rather than intramuscularly? I am aware, of course that the serum must be sterile and the Wassermann reaction negative but I was wondering whether there was any danger from serum accidents and serum sickness when human serum was repeated at rather frequent intervals. Please omit name and address.

M D, Ohio

ANSWER—1. There is probably little danger in giving properly prepared and preserved convalescent human serum in proper doses subcutaneously or intramuscularly at intervals of say one month. It is true that cutaneous and other reactions have been observed after the injection of human serum at frequent intervals.

2. It is possible to transmit allergy passively by injections of human serum. For instance, the serum of a person sensitive to horse emanations (horse protein) may transfer such sensitiveness passively on injection into a second person.

3. Most likely subcutaneous injection of serum would be less painful than intramuscular.

MARRIAGE AND SYPHILIS

To the Editor—A brother and a sister, aged 23 and 27 years have had congenital syphilis with a plus four Wassermann reaction. They have each had about thirty injections of arsphenamine and probably about twenty injections of a bismuth compound. They still have plus Wassermann reactions. They haven't had any treatments for six months. The woman who is to be married wants to know if it is safe in the first place and if she needs any further treatments. She is in perfect health otherwise. Please give me your advice about further treatments in these cases. Kindly omit my name.

M D, District of Columbia

ANSWER—Much will depend, in this instance, as to whether the patients have had lumbar punctures. It is known that the Wassermann reaction in a case of congenital syphilis is slow in its response to treatment. If the patient has had reasonable antisyphilitic treatment the tendency is more and more to ignore the blood Wassermann reaction. If the lumbar punctures were negative, it probably would be well simply to give each one of the patients a course of bismuth salicylate injections intramuscularly, eight injections each, twice a year for the next year.

With the sister, if she marries and becomes pregnant, there would be no harm, certainly with the first one or two pregnancies, in giving her two short courses of bismuth salicylate injections during the pregnancy. She should not hesitate to marry. Of course, the disease is not transmissible to the prospective husband, and transmission of heredosyphilis is problematic and is looked on askance by most syphilologists.

TOLERANCE TO MORPHINE

To the Editor—Is it possible to estimate or is there any average limit to the tolerance of morphine? In other words given two patients, one taking 6 grains (0.4 Gm.) daily and the other taking say 15 grains (1 Gm.) daily can you tell me if it is necessary to produce the same sense of well being for the second patient to take that much more or is there a top limit to any individual's tolerance? I am trying to find out how to estimate how much morphine might be wasted in the mental effect in addicts. Please omit name.

M D Tennessee

ANSWER—It is impossible to state the upper limit. The average may be placed at between 1 and 2 Gm. daily, though the dose may become as high as 4 or 5 Gm. and even exceed this figure. The addict finds it necessary to take an increasingly larger amount of morphine to produce the same degree of euphoria and to antagonize the withdrawal symptoms. As tolerance does not occur to the convulsive effects of morphine, this would set the upper limit to the dose that can be tolerated. Data are not available to state this dose categorically, because death usually occurs before this dose is reached.

HAZARDS OF WAX SPRAYING IN PRINTING INDUSTRY

To the Editor—An inquiry has come to my desk as to the possible harmful results arising from wax spraying in the printing industry. We do not use this method at the Government Printing Office and therefore have no data on the subject. Certain investigations made in one of the larger printing plants in England seem to point to harmful results to workers even to the extent that cancer may follow its use. Have you any data of investigation made along this line?

D P Busn M D, Washington D C

ANSWER—According to the U S Bureau of Standards (Lewkowitsch Chemical Technology and Analysis of Oils, Fats and Waxes, ed 6, New York, Macmillan Company, 1923, p 281) (1) printers' wax consists essentially of ozokerite, a natural bituminous product, waxlike, occurring near petroleum springs. Ozokerite used in this country is obtained from Utah and from Poland. It is freed from asphalt and minerals and is then mixed with beeswax, paraffin rosin, petrolatum, turpentine and burgundy pitch. No injurious action on the skin should follow contact with these substances. None of them are cancer producing. British printers' wax may differ from American and possibly may contain some of the carcinogenic agents that are present in the final products of tar distillation. It is well known that the oil pressed out in the final stage of paraffin production is carcinogenic (Heller, *Imre Occupational Cancers, J Indust Hyg* 12 169 [May] 1930).

ANTIRABIC TREATMENT

To the Editor—I have a patient who was exposed to rabies in December 1934. I gave him fourteen daily doses of an antirabies vaccine made by Jensen Salsbery of Kansas City which product he wished to take the last injection being on Jan 7 1935. He took the vaccine without difficulty except for rather severe local reactions. Recently he contaminated an abrasion on the fingers with saliva from a dog which today developed rabies. He did not apply any antiseptic to the open lesion on the fingers but did use soap and water. The question is whether he should have another course of vaccine. Articles to Beckman and Musser state that protection lasts for twelve to fourteen months. The patient is naturally very worried and wants to take further vaccine but does not wish to run even a small chance of postvaccinal paralysis if it is not necessary.

ALEX R FREEMAN M D, Albany Ga.

ANSWER—The patient will not require further antirabic treatment. Immunity from the treatment in January will protect against the exposure in May. Marie has found complete immunity in dogs for eighteen months. Immunity in man lasts for at least twelve to fourteen months.

BRITTLE FINGER NAILS

To the Editor—A woman aged 32 otherwise in good health is suffering from extreme brittleness of the fingernails. There is no associated pathologic condition of the nails. The brittleness always more or less troublesome has of late years become more so to the extent that it is impossible for her to keep them from cracking and breaking. Naturally being a woman and fastidious she is much concerned. The literature that I have reviewed on the subject is vague as regards etiology and offers nothing in therapeutics. I have prescribed various calcium compounds and vitamin concentrates empirically and have given mild sedatives without any appreciable effect. As I said thorough examination reveals no apparent somatic disturbance other than the complaint mentioned or neurosis. I should be grateful for any comment you may be able to make as regards etiology prognosis and treatment. Please omit name and address.

M D New York

ANSWER—The etiology of this type of nail defect is indefinite. One must rule out the contributory role that nail polishes and polish removers assume and caution the patient against their use. Hypovitaminosis is also a possible factor and vitamins B and D should be given. The daily massage of bland oil into the nails is also of value.

SCARLET FEVER IMMUNIZATION

To the Editor—I would much appreciate information concerning the frequency severity and duration of reactions to scarlatina immunization injections. Has there been any recent modification of toxin or the technique to reduce these reactions?

H A WILDMAN M D Sterling Ill

ANSWER—General reactions to scarlet fever toxin in active immunization against the disease occur in about 10 per cent. There has been no recent modification of the toxin or the technique. That the reactions are not a serious obstacle to immunization would appear to be indicated by the fact that the use of scarlet fever toxin has doubled within the last two years.

SIMULTANEOUS SCARLET FEVER AND GERMAN
MEASLES

To the Editor—At the present time there is a mild epidemic of German measles in this vicinity. Recently two brothers, aged 8 and 10, patients of mine, exposed to this infection with others developed a typical morbilliform rash, blepharitis, epiphora, slight fever, malaise, coated tongue with red edges and a slight dry cough. The rash spread from the face downward, clearing above as it progressed below. In several days they both felt as well as ever and all the rash was gone. There was no glandular involvement. About two weeks later one of the boys who a year ago had a severe urticaria following an injection of tetanus anti-toxin (he was immunized three years ago against diphtheria) developed a definite peeling of the palms of both hands. It was then recalled that mixed in with the morbilliform rash had been a finer, malarial one. A cough was present for about one week at this time. What is the real diagnosis in this case? Please omit name. M D Massachusetts

ANSWER—The description indicates that the one boy had both scarlet fever and German measles.

BURNS FROM PERMANENT WAVE MACHINE

To the Editor—I am seeing an increasing number of scalp burns due to the so-called permanent wave machines. In all these burns I have had difficulty in bringing about healing and I have used everything that I can find both old and new without any striking result. These burns are usually round and of a third degree type with little or no tendency to heal. I understand that the hair is pulled so tightly in these machines that there is little or no feeling in the scalp, hence the great possibility of burning before subjective evidence. Any advice you may give me in this regard I will appreciate. Please omit name.

M D West Virginia

ANSWER—Burns from the so-called permanent wave machines are not electrical burns but due to heat, complicated with a strongly alkaline solution used to soften the hair. These burns are slow to heal because of their depth. The scalp is not very sensitive and the tension may lessen its sensitivity. We know of no method of hastening the healing process. Ordinary burn treatment is all that is indicated.

REACTIONS TO DICK TEST

To the Editor—Can you give me information as to what the expected percentage of positive reactions to the Dick test would be in the age group of 15 to 20 years? Please omit name. M D Illinois

ANSWER—Depending on previous environment, persons in the age group from 15 to 20 years may show positive reactions in from 40 to 60 per cent. If there has been a recent epidemic in the group and the individuals live in dormitories so that contact has been close, the incidence of susceptibility may be as low as from 10 to 15 per cent.

USE OF SCARLET FEVER ANTITOXIN

To the Editor—What is the present day opinion of the advisability of administering 2,000 units of scarlet fever serum for scarlet fever in country practice? J D Michie M D Childress Texas

ANSWER—Two thousand units of scarlet fever antitoxin is inadequate dosage for the treatment of scarlet fever. This is the usual prophylactic dose.

SENSITIVITY TO LIVER EXTRACT

To the Editor—The query on the possible sensitivity to liver extract (THE JOURNAL June 1, p. 2019) prompts this brief note. I had been treating three pernicious anemia patients with Lederle solution liver extract parenteral 3 cc. vials. The injections were given at three day intervals. No patient showed any untoward reactions for the first six injections. Following the seventh injection in one patient a generalized urticaria appeared within eighteen hours. Ephedrine by mouth was sufficient to control this. The urticaria recurred after the eighth and ninth injections. It did not occur however following the tenth injection which consisted of solution liver extract Lilly nor has it recurred since the patient has been receiving solution liver extract Lederle for oral use.

MEYER BLOOM M D Johnstown Pa.

ROENTGEN RAYS FOR PROSTATIC HYPERTROPHY

To the Editor—My attention has recently been called to an answer given under Queries and Minor Notes in THE JOURNAL, March 30, concerning the use of roentgen rays in the treatment of benign hypertrophy of the prostate. The answer given hardly represents an accurate statement of the facts. Roentgen treatment has been used to a considerable extent for benign hypertrophy of the prostate and with a considerable degree of success. While it may be literally true that the size of the gland may not be greatly reduced by such treatment, there is no question that in a considerable proportion of cases the symptoms are relieved sometimes for prolonged periods. A considerable literature on this subject has already accumulated.

Medical Examinations and Licensure

COMING EXAMINATIONS

AMERICAN BOARD OF OPHTHALMOLOGY The Cincinnati examination previously announced will not be held. The next examination will be given in St. Louis, Nov. 18. *Application must be filed before Sept. 15.* Sec. Dr. William H. Wilder, 122 S. Michigan Ave., Chicago.

AMERICAN BOARD OF OTOLARYNGOLOGY Cincinnati, Sept. 14. Sec. Dr. W. P. Wherry, 1500 Medical Arts Bldg., Omaha.

AMERICAN BOARD OF PEDIATRICS Seattle, Aug. 8. Philadelphia, Oct. 10, and St. Louis, Nov. 10. Sec. Dr. C. A. Aldrich, 723 Elm St., Winnetka, Ill.

AMERICAN BOARD OF RADIOLOGY Detroit, Dec. 12. Sec. Dr. Byrl R. Kirklin, Mayo Clinic, Rochester, Minn.

CALIFORNIA Los Angeles, July 22-25. Sec. Dr. Charles B. Pinkham, 420 State Office Bldg., Sacramento.

CONNECTICUT Endorsement Hartford, July 23. Sec. Medical Examining Board, Dr. Thomas P. Murdock, 147 W. Main St., Meriden.

NATIONAL BOARD OF MEDICAL EXAMINERS The examination will be held in all centers where there are Class A medical schools and five or more candidates desiring to take the examination, Sept. 16-18. Ex. Sec. Mr. Everett S. Elwood, 225 S. 15th St., Philadelphia.

NEVADA Reno, Aug. 5. Sec. Dr. Edward E. Hamer, Carson City.

OREGON Basic Science Corvallis, July 27. Sec. Basic Science Examining Committee, Mr. Charles D. Byrne, University of Oregon, Eugene.

PUERTO RICO San Juan, Sept. 3. Sec. Dr. O. Costa Mandry, Box 536, San Juan.

Montana April Report

Dr. S. A. Cooney, secretary, Montana State Board of Medical Examiners, reports the written examination held in Helena, April 2-3, 1935. The examination covered 10 subjects and included 50 questions. An average of 75 per cent was required to pass. Four candidates were examined, all of whom passed. Eight physicians were licensed by reciprocity and 1 physician was licensed by endorsement. The following schools were represented:

School	PASSED	Year Grad.	Per Cent
Loyola University School of Medicine		(1922)	75.2
Northwestern University Medical School		(1935)	83.2
University of Minnesota Medical School		(1934)*	75.8

Book Notices

Annual Reprints of the Reports of the Council on Pharmacy and Chemistry of the American Medical Association for 1934 with the Comments That Have Appeared in The Journal. Cloth. Price \$1. Pp 135. Chicago: American Medical Association 1934.

Each succeeding volume of reports of the Council reveals more of the long and successful fight in the interest of rational therapeutics. The Council is no longer chiefly concerned with noisome proprietaries and yet this latest volume contains reports on such articles as "Vita-Cell," a secret preparation marketed with exaggerated claims, and "Raylos," a shotgun preparation marketed in a way to promote its ill advised use by the public. Most of the "unacceptable" reports in this volume are concerned with products that may have some merit but are not offered to the public in a way which experience has taught the Council is necessary before a therapeutic agent is acceptable. Such products are Iodine Dusting Powder (Sulzberger), rejected for lack of clinical evidence of its advantage over one of its constituents, Pernoston, rejected because of lack of clinical evidence to justify routine intravenous injection of barbitals compounds, Di-Hydranol, a claimed bactericidal agent proposed for use as an "intestinal antiseptic," a claim not supported by sufficient clinical evidence, and Squibb Adex Tablets a product containing a concentrate of vitamins A and D, for which the firm could not agree to adopt a more informative name.

To those who have followed the Council's investigation of B acidophilus therapy, the report "Acidophilus Bacillus Liquid-Mulford and Mulford Acidophilus Bacillus Block Omitted from N N R" will be of interest. The Council has apparently not yet reached an ultimate conclusion concerning acidophilus therapy, but it has for years held that no product could be expected to be of value unless it could show at least one hundred million viable B acidophilus organisms at the "date of expiration." Competent bacteriologic examination showed that the two preparations here reported were inferior to this standard. Further grounds for omission were the failure of the manufacturer to comply with certain stipulations in regard to labels and advertising. Another noteworthy omission is that of Alpha-Naphco and its dosage forms omitted because the Council on reconsideration found that it is a weak antiseptic.

The Council also issues preliminary reports, which define the status of new preparations for which the evidence is not yet sufficient to justify their presentation to the medical profession generally. Preliminary reports do not imply rejection but rather postponement of consideration until more evidence is reported by competent investigators. These reports are the outposts of therapeutic progress and as such are valuable sources of information to physicians. In this volume there are preliminary reports on Adrenal Cortex Extract, concerned mostly with scientific terminology, Cysteine Hydrochloride, Dihydroxy-Anthranol (Anthranol), Gastric Mucin, Hemoprotein (Brooks), Phenylmercuric Nitrate and Phenylmercuric Chloride.

Illustrative of the Council's efforts to keep those concerned informed of the basis for its actions are the "Recent Revisions or Elaborations of the Council's Rules of Interest to Manufacturers and the Medical Profession," which have appeared in the last two volumes. These inform the profession of the various problems which arise and the care given to their consideration. To be commended also is the "Report on Sterility of Ampule Preparations."

Radologie olinique du tube digestif. Publiée sous la direction de M^{re} Pierre Duval J Ch Roux et H Bécère. I. Estomac et duodénum. Par Pierre Duval Jean Charles Roux et Henri Bécère. Fasc. I. Estomac. Fasc. II. Duodénum. Second édition. Cloth. Price 330 francs. Pp 252 with illustrations. Paris: Masson & Co 1935.

The first edition of this study, published seven years ago, has been completely revised and the newer methods are included. New chapters on such subjects as gastric syphilis and gastritis and additional material on diaphragmatic hernia and pyloric stenosis have made the work complete. The publication is in two large volumes, one of 252 double pages on the stomach and a volume of 114 double pages on the duodenum. A com-

plete description of the methods of fluoroscopic examination used by the authors is given. These methods are essentially the same as are being used in the better clinics of this country, with emphasis especially on the observations in both upright and horizontal positions and in the various oblique and tilted positions. The authors have also used the introduction of a mixture of barium sulphate solution and air into the stomach to good advantage in bringing out questionable lesions that may be ordinarily covered over with a thick layer of heavy barium solution. Both volumes are liberally illustrated with fine reproductions of x-ray plates illustrating every possible lesion of the stomach and duodenum that can be encountered as well as diagrammatic studies of every type of gastric and duodenal lesion. The two volumes make a complete x-ray atlas on the stomach and duodenum, which can be referred to either by the skilled x-ray student or by the novice in roentgen diagnosis to good advantage. The books are beautifully bound, printed on excellent paper and written in simple, understandable French.

Social Work Year Book 1935 A Description of Organized Activities in Social Work and in Related Fields. Edited by Fred S. Hall. Third issue. Cloth Price \$4. Pp 698. New York: Russell Sage Foundation, 1935.

The third issue establishes this year book as the standard reference work in the special field of social work. If one recognizes and allows for the attitude from which nearly all social workers approach the subject treated, such a volume is of considerable value. Each article is followed by a fairly complete bibliography. However, the same bias that runs through the articles tends to the omission from the bibliography of works that do not agree with the attitude of the authors. The article on medical care is written by Michael Davis and Marcella Rivers and takes its information largely from the publications of the Committee on the Costs of Medical Care. It is not accurate in its description of the Michigan Mutual Health Service and the situation in Washington and California. There is no mention of the fact that the insurance plans in Washington and Oregon were forced by compensation laws and are by no means welcomed by the physicians. Compulsory health insurance is treated by I. S. Falk, who devotes a considerable portion of the space to the "Model Bill of the American Association for Social Security." It is not probable that most physicians will turn to this work for authoritative information on medical matters, but it is indisputably the most authoritative work in its own special field of social work. It is divided into two parts. The larger part of the book consists of a treatment in alphabetical order of various subjects, the second section is a "directory of agencies." This section gives a brief summary of the organization and objectives of what seems to be a fairly complete list of the agencies concerned in any way with social work.

Repos physiologique du poumon par hypotension dans le traitement de la tuberculose pulmonaire. Observations cliniques et physiologiques. Par F. Parodi, agrégé de l'Université de Milan. Traduit par Totiana Parodi. Préface de E. Sargent. Paper Price 48 francs. Pp 232 with 59 illustrations. Paris: Masson et Cie, 1935.

This book is a well constructed, simply written discussion of the principles underlying the employment of pneumothorax in pulmonary tuberculosis. The description of the clinical technique and management is plainly based on extensive experience. In the earlier chapters, however, the discussion of mechanical principles is unnecessarily argumentative and academic. The author takes issue with the view that the negative endopleural pressure depends on the elastic tension of the lung and cites experiments both by himself and by others purporting to show that the pressure is not equal in all parts of the cavity and that therefore lung expansion cannot be equal in all parts. In this he disregards the unequal excursions of different parts of the thoracic wall. He ascribes to the weight of the lung the entire role of creating endopleural pressure, which would therefore be changed by variations in the weight of circulating blood. Also he denies, apparently on purely speculative grounds, that diffusion of fluid out of the pleural cavity can create negative pressure. This reveals some lack of familiarity with the physical laws governing diffusion. Still further he discusses the density of the lung tissue as a factor in producing endopleural pressure, overlooking the fact that density is one of the

factors contributing to elastic recoil. The ultimate conclusions and their applications are not, however, invalidated by the academic digressions. The book is well illustrated, and numerous references are cited. Withal the work is worthy of consideration by those interested in the clinical problems involved.

The Care of the Aged, the Dying and the Dead. By Alfred Worcester, M.D. Sc.D. Henry K. Oliver, Professor of Hygiene, Harvard University. Paper Price \$1. Pp 77. Springfield, Ill. and Baltimore: Charles C. Thomas, 1935.

This book considers certain obligations of the physician, which are obvious when attention is called to them but which are in a way extramedical. They have to do with ministrations of sympathy and comfort for the aged and dying and of the disposition of the dead. The attitude of its author is that of a wise practitioner of long experience and of sympathetic disposition. It will bring to every reader the suggestion of activities in emotional situations where sympathy is useful and ought to be appreciated, and the realization that he should be more thoughtful of his obligations in such situations than he is likely to be. It is a wholesome little book and worthy of reading by physicians and laymen.

Scritti medici in onore di R. Jemma nel XXX anno d'insegnamento. Redatti dal Prof. I. Nasso e dal Dott. E. Schwarz. In two volumes. Paper. Pp 1438 with illustrations. Milan: Cromotipia Ettore Sormani, 1934.

This is a beautifully prepared festschrift of the eminent Italian professor of pediatrics. It is bound in stiff paper and contains contributions from 144 pediatricians from all over the world, most of whom of course are Italian, but many French, German, English, American, Scandinavian and South American contributions are represented. The articles are published in Italian, English, French, German and Spanish. The publication is most elaborate. The articles cover a range of subjects that touch on almost every phase of pediatrics.

Selection of Risks for Life Insurance. Health Insurance, Accident Insurance. By Harry W. Dillingham, Vice President and Medical Director, Continental Casualty Company and Continental Assurance Company. Cloth Price \$5. Pp 380. Cincinnati: National Underwriter Co., 1935.

Without preface or introduction, the author proceeds directly to a discussion of the selection of risks for insurance, with an explanation of the duties of the medical examiner, inspector and home office selector. The importance of the personal and family histories and the influence of race, occupation, environment, habitat, morals, finances and physical status are then discussed. The remainder of the book is devoted to a discussion of the various diseases and conditions affecting risks in the light of the accumulated experience of life insurance companies in the past. These factors are arranged alphabetically, permitting quick reference. The sections dealing with albuminuria, alcoholism, amebic dysentery, aviation hazard, blindness, blood pressure, claim psychology, gallbladder disease, glycosuria, heart disease, peptic ulcer, pneumoconiosis, pulmonary tuberculosis and weight are of particular interest. The book is highly recommended and should prove useful to those engaged in life insurance work.

Limbs for the Limbless. A Handbook on Artificial Limbs for Laymen and Surgeons. By John Culbert Farley, Ph.D., Instructor in Orthopedic Surgery in the Post Graduate Medical School, Columbia University. Introduction by Fred H. Albee, M.D. Sc.D., LL.D., Chairman of the New Jersey State Rehabilitation Commission. Cloth, Price \$2. Pp 104 with illustrations. New York: Institute for the Crippled and Disabled, 1934.

This small book presents a strong argument for the universal use of artificial limbs whenever the type of amputation makes it possible. Children should not be allowed to wait until full growth before being furnished with a suitable prosthesis, and adults should be urged to abandon crutches and use artificial legs. The history and development of prosthetic apparatus is lightly sketched and the generally desirable features of artificial legs and arms are emphasized without mention of any specific varieties or manufacturers. The limitations of apparatus are well described in connection with the various sites of amputation, and this is the most important portion of the book from the standpoint of the patient. The points of election for amputation are shown by the familiar and valuable illustrations from the War Department's Review of War Surgery and Medicine, 1918. The preparation and care of the stump is correctly described. The importance of 'provisional'

prostheses in reducing and shaping the stump is well emphasized and might well have been supplemented by a detailed statement of the method of making these "pilons," although the author remarks that this probably is not the place to describe the technic. The appliances for hand and arm amputations are well discussed and rightly sound a note of pessimism regarding the value of the cineplastic procedures of Vanghetti and Sauerbruch. The more complicated mechanical hands are not as useful as at first they seemed to be, and the emphasis is properly laid on the more simple hooks and tool holders, with a "dress" arm merely for the sake of appearance. The book is worth reading by patients as well as by surgeons.

The Anatomy of the Leg and Foot for Students and Practitioners of Chiropody. By Philippa N. Vaus. M.R.C.S. L.R.C.P. Lecturer to the London School of Chiropody. With an Introduction by A. T. Compton. F.R.C.S. Lecturer in Anatomy to King's College, London. Cloth. Price \$2. Pp. 107 with 47 illustrations. Baltimore: William Wood & Company, 1935.

This book was written for students and practitioners of chiropody. The first essential to good chiropody is a thorough knowledge of the anatomy of the leg and foot and some knowledge also of general anatomy. The book can be highly recommended as fulfilling the purpose for which it was written. The illustrations are satisfactory and the text is easily read. There is an appendix containing the B.N.A., revised and old terminology of anatomic structures. The author believes that chiropody should not be practiced by any one without a recognized diploma. The public will realize that as much harm can be done by an ignorant and unskilled chiropodist as by an unqualified dentist. The author looks forward to the day, which she hopes is not far distant, when a recognized diploma will be necessary for the legitimate practice of chiropody in England. She emphasizes the desirability of such a situation and the benefit to be derived for public and practitioner alike.

Medicolegal

Hospitals Burns Inflicted on Unconscious Patient.—After a cesarean operation in the hospital—defendant, and while the patient was still unconscious, hot compresses and hot water bottles were applied and the patient was burned. She and her husband sued the hospital, joining with it as a defendant one of two special nurses whom the hospital had called in to care for the patient. The jury returned a verdict in favor of the nurse, but against the hospital. The hospital thereupon appealed to the district court of appeals, second district, division 2, California.

The record does not show by whom the compresses and hot water bottles were applied. The hospital contended, however, that the special nurses on the case were not employees of the hospital so as to render it liable for their negligence. The appellate court held to the contrary, on authority of *McBride v. Clara Barton Hospital*, 75 Cal. App. 161, 241 P. 941. The jury was justified in concluding from the evidence that the patient's injuries were caused either by a nurse regularly employed by the hospital or by one of the two nurses specially engaged by the hospital. The verdict that absolved the special nurse who had been joined with the hospital as a defendant did not exonerate the hospital, for she was not the only nurse caring for the patient when the burns were inflicted.

The patient's physician and her attending nurses testified that her injuries were burns. The hospital produced an expert witness who testified, in response to a hypothetical question, that the condition described could have been a herpetic condition. The hospital then complained, on appeal, that the trial court, in instructing the jury, assumed that the patient's injuries were burns. But, said the appellate court, the expert witness produced by the hospital did not see the patient, and in the absence of evidence more substantial than that offered by the hospital, the court had a right to conclude that the injuries were burns.

The trial court did not err in instructing the jury on the doctrine of *res ipsa loquitur*, for the patient was unconscious during the time the injuries were being inflicted and that doctrine was clearly applicable. Neither did the trial court err in

giving certain instructions that the hospital contended made it and its nurses, in effect, insurers against negligence and burns, since the instructions complained of, considered in the light of the court's entire charge, could not have misled the jury on any essential legal principles. When a patient is unconscious after an operation and those charged with caring for her, knowing her helpless condition, use hot compresses and hot water bottles, they must use them in such a way and keep such watch over them as not to burn the patient.

For the reasons stated, the judgment against the hospital was affirmed.—*Timbrell v. Suburban Hospital, Inc. (Calif.)*, 36 P. (2d) 435.

Malpractice Reliance on Sponge Count by Nurses No Defense.—The patient and her husband sued the physician—defendant, alleging that in the performance of an abdominal operation a sponge was left in the patient's abdomen. The "sponge" was described as "a gauze pack or pad, six inches wide and about eighteen inches long—6 ply gauze in thickness, with a tape attached to one corner, about four inches long." To it was attached a metal ring. From a judgment for the plaintiffs, the physician appealed to the supreme court of New Jersey, alleging that the trial court erred in not directing a verdict in his favor.

The physician—defendant operated on his patient in a public hospital, over which he had no control, and the hospital supplied two nurses from its staff, to assist in the operation. He asserted that by recognized custom it was the duty of the nurses who assisted him to keep count of the sponges and the duty of the head nurse to report, before the operation wound was closed, as to the correctness of the sponge count. He contended that the head nurse had so reported to him in this case and he argued that he was entitled to rely on that report, as the nurses were not in his employ or furnished by him. He claimed that under the circumstances he was not required to make any extended examination of internal conditions after the operation and was not responsible for an erroneous count of the sponges used. Any duty of independent examination that rested on him, he contended, was shown to have been adequately performed so that nothing in the evidence justified the jury in finding that he was negligent, and the case therefore should not have been submitted to the jury.

The supreme court of New Jersey, however, did not agree with the defendant's contentions. Notwithstanding the nurse's count, said the court, a duty remained with the defendant to examine independently, to make sure that no foreign body remained in the abdominal cavity. The existence and non-discovery of so considerable an object as the pad that was left in the patient's body in this case, particularly in view of the testimony of expert witnesses as to the usual practice of an independent examination by operating physicians, presented a case for submission to the jury. The very fact that the physician—defendant was operating with nurses not in his employ nor, so far as appears, of his own selection, seemed to the court to give emphasis to this view.

The court affirmed the judgment in favor of the plaintiff.—*Starwicz v. Kelley (N. J.)* 174 A. 896.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to *THE JOURNAL* in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Neutral Chloride in Secretions of Stomach and Duodenum.—In a series of ninety-five experiments on dogs, Wilhelm and his associates found that the neutral chloride concentrations of the nonacid secretions of the stomach and the mixed duodenal secretions were approximately the same, the average values ranging from 358 to 307 mg per hundred cubic centimeters. When the nonacid secretions of the stomach or the duodenal secretions are mixed with tenth normal hydrochloric acid, only about one third of the neutral chloride fraction represents neutralized hydrochloric acid.

Hypertonic Sucrose Solution Intravenously to Reduce Cerebrospinal Fluid Pressure.—Bullock and his co workers compared the effects of intravenously injected sucrose, dextrose and sodium chloride solution on the cerebrospinal fluid pressure under experimental conditions. Spinal fluid pressures were measured aseptically for from ten to thirteen hours on dogs anesthetized with sodium amylal. Control experiments showed a gradually rising pressure during the period of observation. There was also a moderate increase in the number of white cells in the spinal fluid, which was not produced by sodium amylal alone. Intravenous injection of 50 per cent dextrose (31 Gm per kilogram) and 30 per cent sodium chloride (0.61 Gm per kilogram) reduced the spinal fluid pressure for from two to three hours; the pressure then rose above the control level. From 3 to 8 Gm of sucrose per kilogram of body weight, injected intravenously in a 50 per cent solution reduced the spinal fluid pressure in from five to eight hours. The magnitude of the fall of pressure (from 50 to 150 mm.) was dependent on the amount of sucrose given and on the height of the initial pressure. Greater effects were obtained with higher initial pressures. Although observations were made for twelve hours

after injection, there was no indication of the beginning of a secondary rise of pressure exceeding the control level, except in three experiments. In these, it could be attributed to definite causes other than the sucrose. Injection of sucrose induced active diuresis lasting about three hours, during which the kidneys eliminated about four times as much fluid as was given intravenously with the sugar. The mechanisms by which various hypertonic solutions reduce cerebrospinal fluid pressure are compared and discussed. While temporarily increasing the circulating plasma volume, sucrose reduces the spinal fluid pressure without a secondary rise.

Radium Dosage and Technic in Carcinoma of Tonsil.—Cutler limits his discussion to certain observations on the effect of the total period of irradiation on the skin, the tumor bed and the local lesion in carcinoma of the tonsil, pharynx and larynx treated by the 4 Gm radium pack. He selected five cases, which are of interest as evidence in the problem of the upper time limit for total irradiation without the production of radiation immunity and as evidence on the dose necessary to produce an epidermitis and the upper limits of safety in massive radium therapy. The lesion was early and localized in one case and advanced in four cases. Complete disappearance of the lesions was accomplished in all the cases by protracted radium pack therapy. The lesions were exposed twice daily and consecutively. The distances were 10 and 15 cm. An epithelitis was produced in every instance and an epidermitis in three of the five cases. These observations are presented to demonstrate a primary disappearance of disease in response

to protracted irradiation. The patients have been free from disease for periods varying between nine and eighteen months. The short interval since treatment permits no deductions on the permanence of the results. These observations, however, seem to confirm the possibility that, if continuity of treatment is observed and the total dose is adequate, the total period of irradiation may be prolonged to forty, fifty or even sixty days without necessarily inducing a radiation immunity. Although it is possible that local recurrences may still develop in these cases because of the short interval of time, it is much more likely that reappearance of the disease—if it occurs—will take place in the form of metastases to lymph nodes outside the field of irradiation or to distant viscera.

Plasma Cholesterol in Tuberculosis and Amyloid Disease.—King and Bruger observed in thirty-four cases of tuberculosis without amyloid disease that the predominating pulmonary lesion was ulcerative tuberculosis associated with a distinctly positive sputum and marked constitutional symptoms. The lowest cholesterol level occurred in one patient shortly before death in which only a trace was found. The highest value was 286 mg per hundred cubic centimeters of blood. There was no apparent correlation between the plasma cholesterol and the age, extent or duration of the disease. In thirteen cases with a cholesterol concentration below 150 mg per hundred cubic centimeters, death generally followed within a month. In the other twenty-one cases with normal or slightly elevated cholesterol levels the mortality over a period of six months was 22 per cent. In four cases, hypocholesterolemia was associated with an early fatal termination. In sixteen cases of tuberculosis with early amyloidosis of the kidney, severe tuberculosis was complicated by incipient renal amyloid degeneration. The amyloid was recognized by a positive congo red test and a constant urinary protein. Cholesterol values were higher in this group than in the previous ones. Only two cases with marked hypocholesterolemia were encountered, both of these terminated fatally within a brief period. The average cholesterol value for the other cases was 228 mg per hundred cubic centimeters. The mortality during a period of six months was 22 per cent in those with normal or elevated plasma cholesterol. The most prominent clinical features of twenty cases of tuberculosis with amyloid nephrosis and edema were general anasarca and marked proteinuria. Pulmonary lesions were usually extensive. In three instances, bone tuberculosis was present. A marked increase in plasma cholesterol, as high as 450 mg, was found, the lowest cholesterol observed at the time of edema was 200 mg. In four cases a fairly severe anemia (60 per cent hemoglobin or less) was associated with hypercholesterolemia. When the prognosis was bad, a tendency toward a falling plasma cholesterol concentration became evident. A falling blood cholesterol was noted in several subjects shortly before death.

Arteriosclerosis in Diabetes.—Rabinowitch studied fifty cases of diabetes, which show that excess blood cholesterol is an important etiologic factor in the production of arterioscle-

rosis in the young diabetic patient. The data also appear to indicate that treatment with the high carbohydrate low calory diet has delayed development of cardiovascular disease in the cases investigated. Time alone and further studies will determine whether this diet can actually prevent premature development of this complication. One of the most constant characteristics of the high carbohydrate-low calory diet is an immediate and sustained decrease of plasma cholesterol. The author believes that this finding is incontestable. Therefore, if the conclusion that excess cholesterol in the blood causes cardiovascular disease in the young diabetic patient is also found to be correct, the outlook of patients with diabetes has been greatly improved. Repetition of these studies is therefore warranted by others with similarly available facilities. In order that other data may be comparable, the method of investigation should be the same, the combined method of detecting arteriosclerosis should be used in every case. This includes a physical examination, examination of the fundi, roentgen examination of the lower extremities for calcification of the arteries, and roentgen examination (6 foot plate) of the heart. Any one method alone or any combination of two or three methods alone does not afford a sufficiently reliable index of the presence or absence of arteriosclerosis. For the estimation of plasma cholesterol, all blood samples should be collected in the fasting state, and in the interpretation of cholesterol data all conditions known to affect the concentration of cholesterol in the blood—that is, whether they increase or decrease it—other than diabetes and arteriosclerosis should be excluded as much as possible. In order that data of different clinics with respect to degree of control of diabetes may be reasonably comparable, the author suggests that the control index reported should be used. It appears to be a reasonably quantitative measure of control of diabetes from a statistical point of view.

Cutaneous Moniliasis Associated with Oral Thrush.—Downing and Hazard observed a case of moniliasis in which there were markedly hyperkeratotic lesions on the face. Mild, general forms of therapy proved effective in the treatment of the lesions of the skin, whereas inhalations of ethyl iodide had no effect. The type of *Monilia* isolated in this case is not usually present on normal skin. The organisms from lesions of the mouth and the face were yeastlike in structure, produced segmented mycelia, did not form ascospores, fermented certain sugars with the formation of acid and gas, did not coagulate milk and were pathogenic for rabbits. The first four of these characteristics are specific for the genus *Monilia* or *Parasaccharomyces*. In view of their pathogenicity for rabbits, as well as the fermentations of sugar, the fungi may be placed in the group *Parasaccharomyces*, described by Nye. Except for the fact that no formation of gas was observed in galactose, these organisms might be positively identified as *Monilia*, type II, described by Stovall and Bubolz, which includes, among other species, *Monilia albicans* Craikii, *Monilia psilosis* Ashfordii and *Monilia pinoyi* Castellani. Since the most characteristic biochemical reactions are obtained in maltose and saccharose, the organism would seem to belong to *Monilia*, type II, in spite of the failure to form gas when grown in galactose. The species *Monilia albicans*, described by Benham, presents the same mycologic aspects as the organisms isolated in this case.

Generalized Sporotrichosis Cured—Report of a Case—Moore and Kile cite a case of generalized, subcutaneous, gummatous, ulcerating sporotrichosis with a possible pulmonary complication and subsequent cure. The condition closely simulated tertiary syphilis, the syphilitic type of sporotrichosis. The organism recovered from an active unruptured lesion was identified as *Sporotrichum Beurmanni*, a species that is considered as doubtfully distinct from *Sporotrichum Schenckii*. The presence of symptoms in the pulmonary apparatus with subsequent and simultaneous cure along with cure of the cutaneous lesions leads the authors to suspect a similar infection. The absence of *Sporotrichum* both in smears and in cultures of the sputum on several occasions cannot be accounted for unless one presupposes, as have several authors, a production of toxin—either exotoxin or endotoxin—which is liberated by the fungus and localized in the lungs. However, the existence of airborne spores indicates the possibility of a pulmonary complication, and the failure to find the organism in a few attempts does not rule out the possibility of infection. The patient was given a saturated solution of potassium iodide up to 40 drops (26 cc) three times a day. The lesions were dressed with a 5 per cent iodine ointment. The medication seemed to have a specific effect in clearing up the subacute inflammatory phases of the infection in the lungs. In a month the skin lesions were almost completely healed but medication was continued for another month. The patient has been free from lesions for two and a half months, without recurrences.

Cardiovascular Syphilis—In the hope of adding to the knowledge of cardiovascular syphilis, Maynard and his associates began a study in 1927 in the clinics of the Brooklyn Hospital for adults with cardiac disease and syphilis. Every patient in the clinic for syphilis who would consent was referred to the clinic for cardiac disease for complete cardiovascular examination. They found that syphilis of the aorta can be recognized much earlier than in the past. In order to discover its presence it is necessary that every syphilitic patient be examined regularly by methods used in making a diagnosis of cardiovascular disease. These examinations should be repeated every six months or once every year. Roentgenograms and fluoroscopic examination provide the most reliable means of deciding whether abnormality of the aorta is present in early syphilis. Heart failure occurs only in those patients in whom syphilitic involvement has passed beyond the stage of simple aortitis. In the patients studied myocardial failure appeared only after the development of aortic insufficiency, aneurysm or narrowing of the coronary arteries. Multiple gummas may be regarded as a cause of heart failure but this condition was not encountered in the present study. It is well known that these four manifestations are late lesions. Symptoms of heart failure usually prompt patients to seek relief in clinics for cardiac disease. Since these tend to occur late in cardiovascular syphilis and since no special routine effort has been made in the past to examine syphilitic patients for evidence of cardiovascular disease, the discovery of aortitis has been delayed. It is probably not true that syphilitic aortitis is a late lesion occurring on the average twenty years after the occurrence of the chancre. It is the authors' opinion that involvement of the aorta begins soon after the chancre has appeared and that, in the past, discovery of the presence of the disease has

been delayed by the late development of symptoms referable to the heart and more especially by inadequate methods of examination.

Experimental Peripheral Gangrene—McGrath derived from his experiments the fact that female rats previously intoxicated with ergotamine tartrate in amounts sufficient to produce gangrene of the tail were protected from the development of the gangrene by adequate amounts of theelin. The chi square test of probability demonstrates conclusively that the results are not attributable to the operation of chance alone. At first glance it would seem that theelin had no protective action on the male rats of the experiment. A mathematical analysis of the mean results, however, indicates that there was a significant delay in the onset of trophic changes in the male rats of the first series receiving theelin as compared with the onset in males not receiving theelin. The delay was not encountered in the later series of males. The discovery of this phenomenon of delay suggests the possibility that theelin may have some effect on the male, if administered in sufficiently large doses. Experiments testing this hypothesis are in progress. The mean times of appearance of the major trophic changes—pallor, cyanosis, blackness of the tail and demarcation of the gangrenous portion—are compiled together with the mean extent of the gangrenous process in the tails under increasing doses of ergotamine. Analysis of these means indicates a significant increase in the speed with which the trophic disturbances occur, varying directly with the increase of the dose of ergotamine. Such a relationship is not apparent in the extent of gangrene. The parallelism between the sex limitation of thromboangiitis obliterans and the protection of the female rats from ergotamine gangrene by an excess of theelin is indicated. It was noted that within this parallelism lies the suggestion that there may be in thromboangiitis obliterans a basic etiologic disturbance which is possibly endocrine, and that the failure of the disease to manifest itself in women or at least its presence in a form so mild as to escape clinical notice may be associated with a protective action of the estrogenic principle of the ovary.

Metabolism in Undernutrition—Strang and his co-workers state that studies of the basal metabolism, nitrogen metabolism and efficiency of digestion of patients with severe degrees of undernutrition showed no abnormalities in the factors that could cause the initiation or persistence of pronounced states of undernourishment. The changes in these three factors which were observed as a result of either the high caloric intake or the increases in weight dependent on it indicated no new principles of metabolism that might militate against the successful treatment of undernutrition by dietary measures.

Fat Tolerance in Hyperthyroidism—Hepler experimented on adult dogs in an attempt to determine the effect of hyperthyroidism on fat metabolism. Twenty-two adult dogs were used; four died of acute thyrotoxicosis and the observations on three others were discontinued because of infections. Thyrotoxicosis was produced by feeding 10 Gm of desiccated thyroid daily with the food. Within a week after the feeding of thyroid was begun the dogs began to show loss of weight, great excitability and diarrhea. The feeding of thyroid slightly decreased the initial blood fat during the first month, while the height of hyperthyroidism was being reached. Continued feeding of thyroid was accompanied by an increase in the initial blood fat above the normal value. During the first period of feeding of thyroid there was a decrease in the tolerance of the animal for fat as demonstrated by the increased curve for blood lipids. The cholesterol values remained within normal limits during the period of feeding of thyroid. During the rest period after the first period of feeding of thyroid, when the animal was in a state of hypothyroidism, the fat and cholesterol values increased. The blood fat and cholesterol decreased during the second period of feeding of thyroid, possibly because in part of a resistance of the animal to a second administration of thyroid. Two explanations for these results are suggested. 1 The thyroid extract injures by its toxic effect the tissue cells, rendering them incapable of maintaining their normal capacity for storing or utilizing fat. 2 In hyperthyroidism the metabolism of the body is established at a higher level and the fuel constituents of the blood—fat and sugar—likewise must be established and maintained at a

higher level in order to sustain this increased metabolism. The author believes that the second explanation is the more satisfactory.

Irradiated Cholesterol in Cure of Rickets in Premature Infants—Tisdall and his associates treated two rachitic premature infants with irradiated cholesterol. They found that the daily administration of 750 international vitamin D units of irradiated cholesterol (equivalent in rat units to 3 drops of viosterol in oil 250 D or 2 teaspoonfuls of a good grade of commercial cod liver oil) produced rapid healing of acute rickets during the winter months. Roentgenograms of both infants taken after irradiated cholesterol had been administered for seven weeks showed good healing of the rickets. At the present time there is evidence that there may be no less than four, and possibly six, chemical substances, each with a different vitamin D effect. The antirachitic potency of viosterol as measured on chickens is only about one-fiftieth that of cod liver oil, unit for unit. Blue fin tuna liver oil, unit for unit, has about one-sixth the antirachitic effect on chickens of cod liver oil. Irradiated cholesterol has been found to be just as effective in the cure of rickets in chickens as cod liver oil. Yoder has reported that cholesterolene sulphonic acid has antirachitic properties when fed to rats. Its action, however, is apparently different from the vitamin D of irradiated cholesterol. From work on human beings Hess has suggested that the vitamin D in irradiated milk is a different substance from the vitamin D in cod liver oil, although recent work by the authors does not substantiate this suggestion.

The Lipopenia of Fever—The results of Boyd's investigation demonstrate that in fever one has to deal with an alteration in the concentration not only of cholesterol but of all

the blood lipids. The onset of fever is accompanied by a temporary lipemia involving all the plasma lipids except cholesterol esters. As fever continues, a lipopenia develops, as the result of a diminished concentration of plasma phospholipids, cholesterol esters and free cholesterol, with an increased concentration of neutral fat. When the temperature subsides, all the values return approximately to the range of those in normal persons. Concurrently with these changes in plasma the concentration of lipids in the red blood cells exhibits exactly the opposite variations. Thus during fever the cellular values of free cholesterol, phospholipid and, usually, ester cholesterol are increased, while the level of neutral fat falls. The volume number of the total fatty acids of plasma rises in the early days of fever, indicating the presence of unsaturated fatty acids, which are replaced by more saturated fatty acids as fever persists. The increase in the lipid content of the red blood cells does not appear to bear any causal relationship to the fall in plasma lipids. The total amount of lipids which these cells are capable of removing from plasma is small, because fats are not oxidized to any extent, if at all, in these cells. In the early days of fever the carbohydrate reserves of the body are burned and the fats are mobilized in the blood. As fever persists the fats are used as fuel and the transport of fatty acids from the depots to the muscles, and so on, becomes very active. The transport fats are rapidly removed from the plasma and the reserves are gradually used up, producing loss in weight and, in extreme cases, emaciation.

Antiabortus Serum—Mitchell and his associates produced a filtrate by growing *Brucella abortus* strain 244 on a 2 per cent glycerin broth for three months. The organisms were separated from the filtrate by passing the liquid through several thicknesses of cotton and subsequently through a porcelain filter. The filtrate was then evaporated in a water bath at 100 C to one tenth of its original volume. Many experiments were conducted with this product. The results demonstrated that this filtrate stimulated the formation of agglutinins and complement fixing substances in the blood of the majority of inoculated animals, these substances making their appearance about the seventh day after the inoculation. This suggested that perhaps a serum containing protective properties might be prepared by inoculating a horse with the concentrated filtrate. Consequently a horse was chosen for experiment. On the thirty-fourth day, complement fixing substances disappeared from the blood. Serum drawn on the eighteenth and the fortieth day was tested on guinea-pigs and was found to possess no protective properties. It therefore appeared that any protective property which a serum might possess was not altogether dependent on its agglutinin or complement fixing substances, also that the filtrate was unable to stimulate the formation of protective substances or constantly to stimulate the formation of agglutinins and complement fixing substances. After a rest of two months the horse was again chosen for experiment. It was inoculated with 1,800 cc. of a culture of *Brucella abortus* 244, grown for ninety-six days. The horse tolerated this massive dose reasonably well. On the seventh day the agglutinin titer rose to 1:40,000 and kept on mounting, until on the nineteenth day it reached almost 1:320,000. No complement fixing substances made their appearance in the blood. Blood was drawn on the nineteenth day, identified as 43 C and tested for protective properties on guinea pigs. When administered to guinea-pigs previous to a challenge inoculation of *Brucella abortus*, serum 43 C conferred a degree of protection. When administered after infection was established,

no protection was conferred. Normal horse serum given before a challenge inoculation conferred no protection. Another normal horse was inoculated on three successive days with *Brucella abortus* 244 incubated ten days. After an interval of nine days, inoculations were used of the same strain of culture but incubated 185 days, 10 cc. was given on two successive days, but the resulting reaction was so marked that only 5 cc was given on the following day. With extreme care the daily inoculation was gradually increased until 1,500 cc caused no reaction. On the sixty-fourth day following the initial inoculation, blood was drawn and the serum tested on guinea-pigs for protective properties. A degree of protection was conferred on guinea-pigs when the serum was administered before inoculation with live organisms. Since the serum gave evidence of possessing protective properties when used on the guinea-pigs, the antiserum has been issued for the treatment of twenty-eight cases of undulant fever. Six cases showed no improvement following the administration of serum. The remaining twenty-two have shown exceptionally satisfactory improvement. In fact, in many of these cases recovery following the inoculation of relatively small amounts of serum, is remarkable.

The Aschheim-Zondek Test with Mature Mice—Sar-Louis states that the Aschheim Zondek test may be performed on mature, even gravid, animals. The reading of the test

may be made after thirty-six hours, although increased intensity and rapidity of luteinization are more striking after from seventy-two to 100 hours. The increased intensity and rapidity of luteinization are indicated by luteinization of interstitial tissue, giving the section a more confluent appearance, luteinization of theca of immature follicles, partial luteinization of a follicle or cyst, so that both granulosa and corpora lutea cells are seen in the same follicle. Increase in the number of corpora lutea atretica and corpora lutea cysts, and increase in the number and size of central hemorrhages. When the animal is not in the preestrous or estrous phase, the presence of hemorrhages alone is significant. These changes are so striking that there is no possibility of confusing them with the physiologic changes observed in the ovaries of mice at any stage of the sexual or estrous cycle. Further experiments are being carried out to determine whether there is any quantitative or qualitative difference between the ovarian reaction in mice following injections of the gonadotropic hormone of the anterior pituitary and those observed following the injection of pregnancy urine.

Convalescent Serum in Preparalytic Poliomyelitis—

The use of serum once paralysis has set in, is contraindicated, as in one of Brodie's monkeys there was no muscular recovery. In two animals 230 and 295 cc of whole blood failed to hold the course of the disease in the late preparalytic stage. Although rapid and pronounced recovery after almost complete paralysis is rare in the experimental disease, it can scarcely be assigned to the effects of serum in one of these animals for it recurred in the animal receiving the smaller dose. One monkey, receiving 135 cc of serum when only a rise of temperature was present was not benefited by the serum, nor was another receiving 208 cc. of serum when only temperature rise cerebrospinal fluid pleocytosis and possibly a transient tremor of

one limb were present. One of these animals was treated at the earliest stage at which a definite diagnosis could be made, the other even earlier, and it is not likely that the course of the disease was any more severe than some of the fulminating human cases—those that really need the benefit of a therapeutic agent. Larger doses of serum than those given to patients and given earlier in the disease failed to halt the progress of the disease in experimental animals. The author's studies confirm the views of Neal and Harmon, who point out that there are no statistical data pointing to the therapeutic value of convalescent serum. The fact that 6 cc of convalescent serum given three days after an extracerebral infective dose prevented paralysis, whereas 75 cc given within the same period but after intracerebral inoculation failed to protect, suggests either that the serum failed to reach the central nervous system or else that the virus was fixed to the cells and could not be dislodged. Andrewes, working with vaccine virus, could prevent infection when the serum preceded the administration of virus, but if given even five minutes after the virus, the serum was ineffective, probably because the virus was already fixed to the tissues. Poliomyelitis virus can spread through the central nervous system of an animal in the presence of demonstrable antibody.

Serologic Types of Hemolytic Streptococci in Cases of Erysipelas—Spicer and her associates isolated sixteen strains of hemolytic streptococci of the beta type from fifty-two cases of erysipelas. Only two strains, a smooth and a coarse obtained from the erysipelatos lesion of the same patient fell into one of their previously determined groups that of type IV scarlet fever. Two other strains absorbed one from each of two serums prepared with the new erysipelas strains. The antibacterial potency of two erysipelas serums prepared by different groups proved to be of low value, as evidenced by protection tests on white mice. A rabbit serum prepared from one of the strains of the new erysipelas series while being highly potent against its own strain (homologous strain), protected against the other new erysipelas strains to about the same degree as did the antiscarlatinal serum. It protected however against the major type erysipelas strain used in the preparation of both erysipelas horse serums to a greater extent than was its own strain protected by either of the erysipelas serums.

Blood Examination of Lead Workers—Lane and Lewy made blood and chronaximetric examinations of 825 men working in four electrical accumulator factories in England. Of the men examined 71.3 per cent were normal by both methods, 14.2 per cent were abnormal by both methods and 14.5 per cent were abnormal by one or the other method only. Chronaximetry showed changes in the nerve irritability in the presence of normal blood observations in men who had in the past worked for many years under unfavorable conditions though they had for at least the last two years worked under extremely good conditions in newly engaged employees who had been unemployed for protracted periods, in certain cases of infection quite independent of lead absorption and in a small group of workers who, in spite of heavy exposure, never developed punctate basophilia although they showed other signs of lead absorption. Pathologic blood changes were present in the absence of nerve changes in workers recently transferred to comparatively dangerous departments (this more subacute form of lead absorption leads to blood changes long before the nerve irritability becomes affected) and in various independent diseases, especially hemorrhages, that affect the blood picture but leave the nerves unchanged. As applied to the individual,

following moderate or heavy exposure punctate basophilia appears more quickly and, following the cessation of exposure, disappears more rapidly than do the nerve changes, changes in the nerve follow exposure at a greater interval and once established are far slower to disappear, and small doses of lead received over a protracted period may lead to nerve involvement without blood changes. Malnutrition, whether quantitative or qualitative, is a factor that may lead either directly or indirectly to abnormal nerve irritability or may facilitate the appearance of nerve changes following lead absorption in the absence of blood changes.

Rhinothorax and Neoplasms of Central Nervous System—Britt cites the three main routes by which the cerebrospinal fluid reaches the nose in rhinothorax and neoplasms of the central nervous system: (1) communications from the floor of the anterior horn of the dilated lateral ventricle through the eroded cribriform plate with the nose, (2) openings from a persistent lumen in the olfactory bulb through the cribriform plate into the nose and (3) an opening from the basal subarachnoid cistern through the cribriform plate into the nose. The first group is the most frequent one. In these cases the increased intracranial pressure causes destruction or atrophy of the cribriform plate. The dura overlying the cribriform plate contains tiny holes, which permit the exit of the olfactory nerves. As in most of the cranial nerves, the pia arachnoid and the subarachnoid space continue for a distance along these nerves. Increased intracranial pressure will erode the cribriform plate and enlarge the tiny holes in the dura. As a result of this the ethmoid mucous membrane, which is interposed between the cerebrospinal spaces and the nasal cavity, gives way and permits the escape of the cerebrospinal fluid through the nostrils. Cerebral symptoms of intracranial pressure disappear as a result of the escape of cerebrospinal fluid. Of the symptoms of intracranial pressure, the most frequent to be relieved are the visual disturbances. The escape of cerebrospinal fluid through the nose is most frequently produced by brain tumors. Two cases are presented. In the first case a midline tumor of the cerebellum produced an internal hydrocephalus. The increased intracranial pressure eroded the lamina cribrosa and permitted the fluid to escape through the nostril. In the second case apparently a deep-seated neoplasm produced rhinothorax. The exact mechanism in this case could not be determined.

The Pathology of Agranulocytosis—Norris presents a review of seventy-six cases of agranulocytosis fifty-four of which came to necropsy. The pathologic lesions usually seen in agranulocytosis are bone marrow hypoplasia, profound neutropenia, secondary anemia in chronic cases, thrombocytopenia, jaundice and hemorrhages glandular and splenic enlargement, ulcerations of the buccal cavity and various parts of the intestinal tract and often thrombosis of the small arterioles. The complicating pathologic changes are abscesses thrombophlebitis septicemia terminal hemorrhage granulopemic pneumonia, either lobar or bronchial type and toxic degenerative changes in the brain, heart, liver adrenals and kidneys. It might be stated that the disease is most often fulminant in character with the organs suffering most severely from infection and general disintegration of necrosing tissues, all of which may obscure the fundamental disease process.

The Wassermann Reaction in Malaria—Saunders and Turner point out that a locality in which yaws is prevalent malaria present and syphilis rare should afford opportunity to determine whether or not malaria causes nonspecific Wassermann reactions because in contrast to syphilis yaws can be diagnosed with accuracy from the history of the disease alone. In a locality in which yaws is endemic patients showing positive Wassermann reactions gave a definite history of yaws in all but about 17 per cent. The Wassermann reactions in a series of patients with malaria agreed almost exactly with the reactions among the general population of the area. In 135 malarial patients seventy of whom had acute febrile manifestations the Wassermann reaction was negative in all cases. In 123 malarial patients whose Wassermann reactions were positive or partly positive yaws or syphilis was the assigned cause of the positive test in all but fifteen cases. Thirteen of these showed consistently positive reactions before and after the attack of malaria. Two had only one observation each. In eight yaws patients who had had positive Wassermann reactions reverting to negative after specific therapy the Wassermann reaction remained negative during subsequent attacks of acute malaria. In two patients who had had yaws but whose Wassermann reactions had become negative, there was slight fixation of the complement with 0.1 cc of serum in each case during an attack of malaria. Most of the patients with anticomplementary reactions had had yaws. The proportion of anticomplementary reactions was higher for the malarial patients than for the general population.

Treatment of Menopausal Syndromes by Diathermy—Robinson groups menopausal disturbances into (1) conditions that are directly due to the menopause, i. e. menstrual disturbances, subjective vasomotor phenomena, myxedema and menopausal arthritis, and (2) conditions which precede the menopause and which are aggravated by it, i. e., backache-cervicitis syndrome and backache-cervicitis-infective arthritis. This classification is etiologic. It is of practical value in that it gives an indication for an effectual line of treatment. He concludes that menopausal and decreaser arthritis are both due to some endocrine disturbance. Menopausal arthritis is amenable to treatment by intrapelvic diathermy, combined sometimes with thyroid extract—a form of treatment that acts in virtue of its effect on the underlying endocrine condition. Toxemias, originating in most cases many years before the onset of the menopause, are aggravated by it, sometimes resulting in quite new additions to the clinical picture, such as arthritis of the infective type. These conditions are also amenable to intrapelvic and intra-cervical diathermy—forms of treatment that act in virtue of their effect on the focus of infection.

Treatment of Lymphatic Leukemia—Israels presents five typical cases of chronic lymphatic leukemia of moderate severity in which previous treatment had not been given. The patients were first given two or three weeks of treatment with compound solution of iodine and afterward x-rays. The results obtained bear out those reported by Friedgood so far as the reduction of the white cell count is concerned, but the beneficial effect on the clinical symptoms was not observed. It does not seem that iodine is of any effective use in lymphatic leukemia; the treatment produces results that compare poorly with those obtained by roentgen treatment even in favorable cases. In the majority of cases of chronic lymphatic leukemia roentgen therapy is capable of ensuring a rapid amelioration and may be unhesitatingly applied; it remains the therapeutic method of choice and iodine does not supplant it. With regard to the etiology of leukemia, it does not appear that the effect of iodine justifies any definite conclusions as to the relation of lymphatic leukemia to hyperthyroidism. Although in some cases the iodine caused a reduction in the white cell count, the failure of symptomatic relief, the lack of improvement in the anemia when present and the uninterrupted course of the condition suggest that the leukemic process itself was unaffected. A direct action of the iodine on the leukocytes seems to be a more likely explanation of this reduction than an action on the disease process. The evidence at present available is certainly not sufficiently clear to justify the use of thyroidectomy as a treatment for leukemia.

Examination of Tuberculosis Contacts—Ward suggests the following modifications in the methods for the examination of tuberculous contacts: 1 To omit the routine overhauling of children. Children should not be neglected in any sense, but

they are already amply covered by the activities and anxieties of parents, teachers, health visitors, school medical officers and practitioners. The clinical examination of a child's chest is of little if any value, and tuberculous disease among children is rare. Delicate children to whom attention is directed should be sent to a preventorium, and children so selected should certainly be examined and roentgenographed. 2 Careful attention should be paid to all contacts past the school age and appointments made for roentgenography. If the roentgenogram shows disease or gives rise to suspicion, this should be followed up appropriately. A poor roentgenogram is worse than useless. 3 The practitioner should take more part in the tuberculosis campaign than at present. It is easy to destroy his sense of responsibility by assiduous departmental work, and with the loss of responsibility goes all interest in the campaign. He could help by securing roentgenography for wayward contacts and for adult members of other families whose appearance or history is suggestive, and also by securing the investigation of workshop or office contacts. Any suggestive roentgen observations can be followed up without difficulty.

Action of Emetine on Activity of Adrenals and Thyroids.—The results that Chopra and his co-workers obtained from their studies show that the epinephrine content in normal rabbits, as estimated by the biologic method, varied from 1.36 to 1.44 mg per gram weight of the gland. With the colorimetric method the results were higher and varied from 3.42 to 3.64 mg per gram of the gland. The epinephrine content

of the adrenals after a series of eight injections of emetine is definitely lower, varying from 0.87 to 1.096 mg per gram weight of the gland. The results as determined by the colorimetric method show that, after a series of injections, the epinephrine content becomes less than that of the control animals and varies from 1.85 to 2.52 mg per gram weight of the gland, as compared to 3.42 to 3.64 mg. These figures, though much higher than those obtained by the biologic method, were, however, sufficiently conclusive as regards the action of the emetine injection on the adrenals. The iodine content of the thyroid is decreased and runs more or less parallel with the epinephrine content.

Incidence of Hepatic Cirrhosis in South India.—Menon and Annamalai state that an analysis of mortality returns of Madras, of the hospital admissions in the Government Rayapuram Hospital and of necropsy records of recent years shows a much higher incidence of hepatic cirrhosis there than in Europe. A study of 177 hospital cases shows that cirrhosis has no special association with alcoholism. The race incidence is more or less in relation to the race proportion in the general population, as judged by the hospital admissions. A careful study of twenty-four specimens of hepatic cirrhosis has shown that the portal type is the most common and that this is similar to the so-called alcoholic type encountered in Europe and America. Mallory's toxic type, anatomically considered, is rare. From necropsy records, some positive evidence is brought forward to show that there is a possible relationship between portal cirrhosis and dysentery, as emphasized by Rogers. But the evidence is more in favor of bacillary dysentery than amebic. This may be given two interpretations. It may be that, in cirrhosis of the liver, the resistance of the intestine is so lowered that dysenteric lesions might occur as a complication, or there may be a more direct etiologic relationship between dysentery and hepatic lesions. Cirrhosis of a capsular type has been observed in three cases of malaria.

Development of Nerve Endings in Fetus.—Hewer states that sensory nerve endings are almost completely developed before the motor endings begin to differentiate. Muscles and nerve endings are differentiated first in the tongue at all stages of the neuromuscular mechanism of the hand and arm is further advanced than that of the foot and leg. An argentophil fiber plexus is already present at eight weeks of development; this may perhaps be the fundamental sympathetic plexus. By twenty weeks of development, pacinian bodies and spindles are well differentiated, by twenty-eight weeks the motor plates are just beginning but are very rudimentary except in the tongue. The functional significance of the ages at which certain nerve endings develop is discussed.

*Plasmacytoma of the Petrous Temporal Bone and Base of Skull. D. F. Cappell and R. P. Mathers—p. 340

Cysts and Retention Abscesses of Nasopharynx.—Kully discusses eighty-eight cases of cysts or retention abscesses of the nasopharynx observed during the last six years. He emphasizes the importance of a more thorough examination of the nasopharynx. The so-called retention abscess of the nasopharynx is not an abscess. It represents an inflammatory closure of the mouth of an adenoid recess or of the pharyngeal bursa with retention of secretion, bacteria, cells and other inflamma-

tory detritus As the cavity dilates, owing to the accumulation of secretion, it partakes of the nature of a cyst The contents appear to be grossly purulent, but on microscopic section there may be few polymorphonuclear cells and a definite cyst wall This condition should be described as an infected retention cyst. Sixty-two of the cases in the report were of this type Postnasal discharge was the most common symptom It was rarely profuse and in two instances had a foul taste and a foul odor It was due to an overflow from the purulent cyst or to its periodic rupture, followed by discharge of contents Some of the discharge came from a frequently associated hypertrophy of the mucous glands of the adenoid or from the mucous cells present in the membrane lining the adenoid crypts Chronic pharyngitis and chronic laryngotracheitis secondary to the post-nasal discharge were invariably present Enlargement and tenderness of the posterior cervical glands were present in twenty-seven patients They were frequently associated with stiffness and rigidity of the muscles of the posterior cervical region Occipital headaches were present in twelve patients and were usually localized at or below the external occipital protuberance in contradistinction to sphenoidal headaches, which are usually diffused over the occiput In some instances the headaches were relieved immediately on puncture of the cyst Mild earache was present in only five patients Tinnitus and moderate deafness were present in seven. In nine patients there was a history of persistent fever of a duration of several months Seven of these patients became fever free after operation and remained so during observation over a period of weeks It is difficult to evaluate the relation of pathologic changes in the nasopharynx to various focal conditions

Plasmacytoma of Petrous Temporal Bone and Base of Skull—Cappell and Mathers report the case of a solitary plasma cell tumor involving the petrous temporal bone, mastoid process and base of the skull The growth resulted in extensive destruction of the bony tissues but did not invade the brain Complete paralysis of the sixth and seventh cranial nerves was produced, and there were also symptoms due to pressure on the ninth, tenth and eleventh nerves in the jugular foramen and to direct pressure on the pharyngeal wall The authors found no record of a similar case in the literature

Mandelic Acid in Treatment of Urinary Infections—Rosenheim used mandelic acid as a therapeutic agent that might replace the ketogenic diet in the treatment of urinary infections It appears to be effective in cases of urinary infection unassociated with urinary obstruction He treated twelve cases of urinary infection six of which were pyelitis of pregnancy His object has been to obtain a high urinary concentration of the acid at a *pn* favorable to its bacteriostatic action The routine method adopted has been to give 12 Gm of mandelic acid daily in divided doses, while the fluid intake is limited to 1 quart. At the same time the acidity of the urine is increased by the administration of ammonium chloride Mandelic acid is readily soluble in water and in the form of the sodium salt is not unpalatable The standard mixture used contains 3 Gm. of the acid to the fluid ounce, just neutralized by sodium bicarbonate (16 Gm) and flavored with lemon One ounce of this mixture is given four times a day, while eight cachets each containing

1 Gm of ammonium chloride, are also given during the day as with the ketogenic diet There is no simple test for the presence of mandelic acid in urine, but extraction of the twenty-four hour urine has shown that on this dosage a satisfactory urinary concentration of the acid is obtained The following method of extraction has been employed The urine was acidified with phosphoric acid, saturated with ammonium sulphate and extracted three times with ether The ethereal layer, dried over sodium sulphate, was evaporated and the residue dried in a weighed flask in an evacuated desiccator The weight of the crude extract has been taken as a measure of the amount of mandelic acid present in the urine Improvement in the successful cases has mostly begun after a few days on mandelic acid, and the urine has usually become sterile within from ten to twenty-one days A striking feature of the treatment has been the rapid improvement in the clinical condition of the patients The toxic effects disappear rapidly The patient's condition is subjectively improved, the headaches and backache diminish, and the frequency of micturition becomes less even though the urine may still be infected The disappearance of nocturnal frequency has been taken as a rough guide to the progress of the treatment Of the six cases of urinary infection, unassociated with pregnancy, all have been clinically improved, while three have been cured

Chronic Arthritis Treated by Gold Salts—Pemberton gives the results of treatment during a period of five years of 100 cases of chronic arthritis treated with three preparations of gold salts In many of the more chronic cases, all known types of treatment for arthritis had already been tried without success and while response to gold is roughly in inverse proportion to the duration of the lesion, a considerable number of these cases exhibited a striking superiority of this to any previous method of therapy Along with gold, in the obese, the diet was reduced in calories and carbohydrate, the former roughly to 1 000 calories daily In the more usual type of rather underweight patients a full diet rich in vitamins A and D was given, but with carbohydrate restriction in those showing a diminished dextrose tolerance If hydrochloric acid was absent from the gastric juice or diminished in it 0.4 per cent of the acid was given by mouth generously When the course of gold has been completed, massage, diathermy and both active and passive movements have usually been started If effusions were large and recurrent, they were aspirated and, whenever possible, deformities such as obstinate knee flexion were treated by firm splinting The preparations of gold have all proved to be toxic to some patients Twelve cases have been cured, thirty-eight very much improved and thirty-eight improved Twelve remain the same

The Posterior Lobe of the Pituitary Gland Its Relationship to the Stomach and to the Blood Picture E C. Dodds G M Hills R L Noble and P C Williams—p 1099

Treatment of Puerperal Fever by Antistreptococcus Serum—Colebrook states that there is no trustworthy clinical evidence that the administration of antistreptococcus serum for the treatment of human infections by hemolytic streptococci has had any specific curative effect The evidence obtained in puerperal fever cases at his hospital suggests that such administration may sometimes have an unfavorable effect on puerperal infections by hemolytic streptococci, and this impression is to some extent supported by the evidence of animal experiments It is in the best interest of the patient suffering from an infection by hemolytic streptococci not to interfere with her immunizing mechanisms until one can be sure that such intervention does no harm Although serums have been produced that would protect animals against infection by streptococci of artificially enhanced virulence, there is no satisfactory evidence that a serum has ever been produced which would afford more than a very slight protection (occasionally) against hemolytic strepto-

cocci freshly isolated from acute human infections and of various serologic types. Similarly there is no evidence that any anti-streptococcus serum has ever exerted a curative effect in animals infected by such hemolytic streptococci freshly isolated from human infections. It is a matter for regret that antistreptococcus serums should have been issued for clinical trial so long before satisfactory experimental evidence as to their curative effects in animals was available or a strong presumption existed (from unequivocal *in vitro* experiments) that such a curative effect would be obtained in man. Until the knowledge of immunization against the hemolytic streptococci has progressed further, it would seem desirable to discontinue the use of anti-streptococcus serums in the treatment (and prophylaxis) of puerperal fever and surgical sepsis.

Posterior Lobe of the Pituitary Gland—The experiments of Dodds and his co-workers on laboratory animals show that the injection of extract of the posterior lobe of the pituitary is capable of causing a temporary inhibition of the secretion of hydrochloric acid, in such a way that the stomach will not react to the histamine stimulus for a period of about six hours. Other workers have called attention to the fact that injection of pituitary extract reduced gastric acidity. Changes occur in the blood of animals injected with this extract. Thus, if a rabbit is injected subcutaneously with the preparation, it will be found on the fifth day that a severe anemia has developed, the blood count being reduced from 6,000,000 down to as low as just over 1,000,000 red cells. The hemoglobin is also reduced but not proportionately to the same extent. On the fifth or sixth days a reticulocytosis appears, which may rise to as high as 50 per cent. There is a marked anisocytosis and a definite macrocytosis. If the animals are killed, obvious changes are seen in the spleen, such as hemorrhagic infarction, and there is evidence of a stimulation of the blood destroying system. The intestine is full of bile, and it would appear that the anemia may possibly be ascribed to an increased blood destruction. If left alone, the animals will recover completely.

*What Becomes of Carbon Injected Intravenously? B. Ménétrel—p. 559.

Carbon Injected Intravenously—As a result of animal observations and a necropsy on an individual previously treated with carbon, Ménétrel concludes that the particles of carbon are deposited especially in the liver, spleen and lungs. It is, however, difficult to determine the laws that govern the distribution of the grains in these tissues. They are doubtless similar to those obtaining with thorium dioxide sol. There are some vascular reactions but never any inflammatory ones, even when the carbon has been fixed for a long time. No system is apparent unless it is the particular affinity of the carbon particles for the reticulo-endothelial tissue. No massing is found near the vessels or lymphatics. It is probably safe to conclude from these observations that carbon causes no lesion, and, having played its part in the defense of the organism against infection, is fixed in certain tissues without producing any inflammatory reaction.

Aleukemic Hepatosplenic Myelosis—Carnot and his colleagues report two cases of aleukemic hepatosplenic myelosis diagnosed during life by means of splenic puncture. The authors say that three points are especially noteworthy from their observations and examinations: 1. Aleukemic myelomatosis is an associated disorder of hepatosplenic coupling. 2. Splenic puncture must be considered an indispensable diagnostic method and is alone capable of serving as a contraindication for splenectomy. It also serves as an indication for roentgen therapy. 3. Puncture alone confirms, during life, the myelo-erythroblastic tissue reaction in the follicular forms of splenic anemia.

Pains in Shoulders and Arms in Heart Disease—Wantoch calls attention to connections between pains in the joints and muscles and heart disease, giving especial attention to the pseudorheumatic pains that most frequently appear in the shoulders and in the upper extremities and are related to angina pectoris. These pains are not only an accompanying symptom of angina pectoris but quite often the initial and for a long time its only symptom. The early recognition of the character of these pseudorheumatic pains is of importance for the treatment. Although the localization in the left shoulder and arm predominates they may appear also in other portions of the body, for instance in the throat, with radiation into the neck, the lower jaw and the teeth, then there may be headaches that are chiefly localized in the occiput. The pains that accom-

pany angina pectoris may appear also in the form of epigastria and hypogastralgia, particularly on the left side, or in the form of pains in the right side of the thorax, or in the right lower or upper extremity, or in portions of it such as the olecranon or the thumb. However, such pseudorheumatic pains appear not only in angina pectoris but also in cardiac insufficiency. The author observed a number of these cases and points out that the cardiogenic pathogenesis of the pains was corroborated by their prompt disappearance following medication with digitals.

Hemoptysis Complicating Injections of Calcium—D. Agostino believes that the cause of hemoptysis immediately following an intravenous injection of calcium in patients suffering with pulmonary tuberculosis is due to one of the three following factors: 1 In cases in which the clinical picture is characterized by the sudden appearance of pain of the lancinating type and circumscribed to a thoracic area hemoptysis is probably due to an infarct caused by the presence in the blood of a small embolus formed during the injection. 2 In cases in which the only clinical symptom is hemoptysis, it is probably due either to the physicochemical changes of the blood produced by the entrance of calcium ions into it or to the rupture of small vessels in the vicinity of the pulmonary lesion. The mechanism of production of the rupture of pulmonary vessels is as follows: Sudden changes of the sympathetic tonus caused by the presence of calcium ions in the blood, result in a transient increase of the blood pressure, during which the vessels near the pulmonary tuberculous lesion which are more fragile than normal vessels rupture and hemoptysis results. 3 In some cases hemoptysis originates in a condition of pulmonary congestion caused by the reaction of the pulmonary tissues to the entrance of calcium in the blood.

*Frei's Intradermal Test and Hellerstrom's Blood Reaction. E. Criscuolo—p 1917

Frei and Hellerstrom's Tests for Inguinal Lymphogranuloma—Criscuolo advises the performance of Frei's test two or three times, with intervals of one or two weeks between the injections, in all suspected cases of inguinal lymphogranuloma. He uses as an antigen sterile pus from a lymphogranulomatous ganglion dissolved in physiologic solution of sodium chloride in the proportion of one part of pus to ten parts of the solution and performs the test by the intracutaneous injection of 0.2 cc of the antigen. The pus is taken from a patient suffering with inguinal lymphogranuloma but not from the one in whom the test is going to be performed. The antigen prepared by the author by desiccating the pus and keeping it in a vacuum and dissolving it in the physiologic solution of sodium chloride just at the time the test is going to be performed, retains its activity for more than one year. Hellerstrom injects Frei's antigen intravenously in his test for the diagnosis of inguinal lymphogranuloma. The first dose is 0.1 cc and increases, if the test is repeated by 0.1 cc. at every new injection to secure positive results that manifest themselves by chills and fever, eight or ten hours after the injection. The reaction is at its climactic point twelve or eighteen hours after the injection, and the condition of the patient returns to normal thirty-six or forty-eight hours later. When the amount of 2 or 3 cc. per injection is reached, the patient reacts no more, except after a period of four or five weeks during which he receives no injections. Hellerstrom's test is harmless and because of the febrile reaction of the organism to Frei's antigen when

intravenously injected, the test is also of a therapeutic value (biologic treatment of inguinal lymphogranuloma). The test is more sensitive than Frei's and gives positive results earlier than Frei's test during the evolution of inguinal lymphogranuloma. The originators of the tests proved that the virus of lymphogranuloma is the common etiologic agent of inguinal lymphogranuloma, climatic bubo, esthiomene, chronic vulvar ulcers with elephantiasis and inflammatory stricture of the rectum.

Results with Traction Treatment of Bone Fractures—Killian reports the results of the traction method of treatment of fractures of the extremities in the surgical clinic of the University of Freiburg (Prof. E. Rehn). Of 1,242 fractures of the extremities, 174 were treated by the method of continued traction or by a traction plaster cast. Twenty-eight of the latter were submitted subsequently to surgical intervention. Ten of these were treated by traction for the purpose of reduction only, and death from tetanus occurred in one, leaving seventeen failures to be accounted for. Analysis of the failures showed that in eight lack of union was due to failures of reduction in spite of maximum traction. All these were fractures of the femur. Interposition of muscle fibers between bone fragments prevented union in three, the cause was edema and thrombosis in two and healing was not obtained in four because of an infection spreading from an infected wound. The greatest incidence of failures with the traction method is encountered in fractures of the femur, the percentage of failures running from 10 to as high as 20. The author emphasizes that the traction method has its definite indication as well as its limitations. In the estimation of the results obtained by any method with fractures of the lower extremities, one must keep in mind not only the preservation of the length of the extremity but the proper alignment and avoidance of joint complications as well. Categorical objection to early operative treatment of fractures is no longer justified. On the other hand, an attempt to obtain reduction by conservative means to the exclusion of all others is equally fallacious. The traction method is frequently a long and expensive one because of the necessity for roentgenologic control and continued supervision. It is contraindicated in diabetes. The author considers the traction plaster cast an improvement on the method because it allows of an early discontinuance of traction.

To What Extent Do Observations on Twins Permit Conclusions in Regard to Hereditary and Environmental Factors? F. Lenz—p 873

Therapeutic Application of Female Sex Hormones—Kaufmann outlines the possibilities and limitations of the therapeutic application of estrogenic and corpus luteum hormones. He discusses the application of these hormones in primary amenorrhea, stressing that this form of hormone therapy produces results in this condition only in exceptional cases. Secondary amenorrhea may be caused by other than genital factors, for instance, by tuberculosis or syphilis. For this reason it is essential to subject the patient to a thorough general examination before the treatment by sex hormones is instituted, for it is advisable only if the general examination is negative. Moreover, it should not be overlooked that an amenorrhea of one or two months duration may develop in normal women, and the author considers hormone therapy unnecessary unless the amenorrhea has persisted for a longer period. He points

out that the administration of the corpus luteum hormone is often unnecessary in the treatment of secondary amenorrhea, large doses of estrogenic substance being sufficient. He discusses the symptoms of abolished ovarian function that develop following castration, during the menopause or in women with hypomenorrhea or oligomenorrhea and shows that the administration of adequate amounts of estrogenic substance tends to counteract these symptoms in a comparatively short period. The fourth group of disorders in which hormone therapy may be indicated are the hemorrhages resulting from glandular cystic hyperplasia of the endometrium. This condition is frequently the underlying cause in the so called juvenile hemorrhages as well as in premenopausal hemorrhages. Since glandular cystic hyperplasia of the endometrium develops under the influence of a relative oversupply of follicular hormone and a deficiency of the corpus luteum hormone, the hemorrhages can usually be arrested by the administration of adequate amounts of corpus luteum hormone.

Relationship Between Tuberculosis and Psychosis II Stefan—p 754

Hypercalcemic and Antitetanitic Effect of Extirpation of Zone of Carotid Gland—Collazo and his associates review the literature on the function of the carotid gland and describe their observations on dogs in which the adventitia of the vessels of the zone of the carotid gland had been removed. They observed a syndrome that was characterized by general debility with reduced muscular tonus, bradikinesia, apathy, paralysis of the eyelids, conjunctivitis, lack of appetite, dyspnea, emaciation falling out of the hair and progressive cachexia. The syndrome terminated in fatal coma. The necropsy of these animals disclosed, in addition to several other changes, a hypertrophy of the parathyroids. The authors observed also that hypercalcemia is a frequent symptom in the animals in which the adventitia of the zone of the carotid sinus had been extirpated. In experiments on another group of dogs, they noted that the attacks of tetany, which were produced by the extirpation of the parathyroids, disappeared when the zone of the carotid gland was likewise extirpated on both sides.

Treatment of Poisoning by Mercuric Chloride—The observation that animals poisoned with lethal doses of uranium could be kept alive when edema formation was induced by Leiter's plasmapheretic method, induced Korányi to try plasmapheresis also in poisoning with corrosive mercuric chloride. Dogs were given lethal doses of corrosive mercuric chloride and after the first twenty-four hours blood was withdrawn every day and large quantities of Ringer's solution were given. When these measures were carried out, the anuria that regularly occurs in poisoning with corrosive mercuric chloride either was entirely prevented or was quickly followed by profuse diuresis. The animals tolerated the treatment well, and after from eight to ten days of treatment the uremic manifestations and the albuminuria disappeared completely, so that the animals could be considered cured. Of the eleven animals that had been given lethal doses, only one died following an anuria of three days' duration. This favorable result in animal experiments induced the author to try this treatment in a patient with corrosive mercuric chloride poisoning. There was beginning oliguria, albuminuria, hematuria, an increase in the rest nitrogen, mercurial stomatitis, vomiting and diarrhea. Under the influence of daily venipunctures (300 cc) and the daily oral administration of 5,000 cc. of Ringer's solution and the intravenous administration of 20 cc. of a 10 per cent solution of sodium chloride there developed a profuse diuresis, so that all uremic and toxic symptoms disappeared and the urine became normal again.

*Treatment of Toxicosis in Nurslings with Intravenous Continuous Drop Infusion I Grube—p 439

*Pathogenesis of Cerebral Complications of Whooping Cough. Carola von dem Esche—p 446

Modification of Blood Sugar by Administration of Fat—Schönfeld calls attention to a report by Knauer and Hirsch-Kauffmann, in which they reported that the administration of oil to children resulted in a hyperglycemia just as did a sugar tolerance test. The author, however, in repeating the tests of those investigators observed that the administration of olive oil was followed by a hypoglycemia, the blood sugar being lowest forty-five minutes after the administration of the oil, that is, at the time when Knauer stated that he observed the highest blood sugar values. Several other investigators have obtained practically the same results with the oil administration as has Schönfeld. On the basis of his own observation and of those reported in the literature he concedes that the administration of oil may occasionally be followed by slight upward fluctuations in the blood sugar, but he states that these fluctuations remain within the physiologic limits. A noticeable decrease in the blood sugar is much more frequent after a fat tolerance test. In animal experiments likewise the blood sugar reducing action of the fat tolerance test was more noticeable than occasional slight increases. However, when oil was administered to rabbits after several days of starvation there frequently was a slight increase in the blood sugar, and if after that the animals were starved further there frequently developed after twenty-four or forty-eight hours an enormous hyperglycemia. This increase in blood sugar is the more surprising since it develops at a time when the blood sugar decreases in starving rabbits as the result of the depletion of the glycogen reserves. The author assumes that this hyperglycemia is the result of the disorganization of the metabolism of the carbohydrate or the metabolism of the liver, instability of these having occurred as the result of the starvation, followed by their being overtaxed by the fat tolerance test.

Continuous Intravenous Drip in Treatment of Toxicosis—Grube resorted to treatment by intravenous drop infusion in sixteen nurslings with toxicosis. She employed the 5 per cent dextrose solution and carefully computed the quantity of fluid for each kilogram of body weight. The results of this treatment were disappointing. The exsiccation improved permanently or temporarily in some of the nurslings, but detoxication was effected in only three of the children. Only two children recovered.

Cerebral Complications of Whooping Cough—In analyzing 1,115 cases of whooping cough, von dem Esche detected 172 with signs of cerebral complications, that is, approximately 14 per cent. The mortality rate was almost 60 per cent in the cases with cerebral complications. She noted a higher incidence in young children, only twenty of the children with cerebral complications were more than 2 years old and the majority were less than 9 months old. The convulsions began frequently in the region of the facial nerve and then changed into generalized tonic-clonic spasms, the duration varying between thirty seconds and several hours. In discussing whooping cough eclampsia, the author means chiefly convulsions. She reviews the literature on the pathogenesis of this condition and then discusses the various pathogenic possibilities in the analyzed material. She knows that the convulsions that develop in whooping cough are not of a uniform nature but may be caused by various pathologic processes. In classifying her material she differentiates two groups. In the smaller group, comprising thirty-eight cases, it was presumably a specific toxic impairment that produced angiospasm and its numerous sequels. In the other group of cases it could not be decided whether the cerebral manifestations were caused by the existing complication (menin-

gritis, predisposition to convulsions, hemorrhages and so on) or whether in addition to these there existed also the same specific impairment of the central nervous system as in the cases of the first group. The author thinks that whooping cough eclampsia as such plays an important part and that it is probably due to the action of the toxins on the regulatory centers of the cerebral vessels, which in turn results in a functional disturbance of the circulation in the form of a prestasis, stasis or angiospasm. Depending on the degree of toxic impairment and the subsequent circulatory disturbance, there develop reparable or irreversible tissue changes. In the first case clinical cure may follow, while in the second case defects remain or death occurs.

Attempt to Treat Nocturnal Enuresis with Testis Hormone F Dietel—p 787

Treatment by Means of Artificial Abscess—Von Blomberg and von Forster say that improvement is often seen in patients with sepsis when local abscess formation takes place. They produce the artificial abscess on the thigh by a subcutaneous injection of from 1 to 25 cc of sterile oil of turpentine. If the reaction capacity is poor, up to 3 cc. may be injected. It is generally advisable to postpone the opening of the abscess until the increased number of leukocytes in the blood begins to diminish again. As a rule the abscess is opened on the tenth day. The authors prefer a puncture incision on the lateral lower edge of the abscess and emphasize that the wound must be well drained. The authors resorted to the artificial abscess at first only in cases with an unfavorable prognosis. Later they produced the abscess also in septic infections, in which an accompanying parenchymal impairment of the liver or kidneys contraindicated intense chemotherapy. The authors treated twenty seven cases, of which three terminated fatally. The fatal cases were one septic angina with incipient agranulocytosis, one sepsis with renal carbuncle, and one old urosepsis with pericarditis and pneumonia. In these cases the abscess did not form. In the cases in which the artificial abscess was successful, the improved general condition indicated that the turpentine abscess increases the defense functions of the organism.

Autotransplantation of Ovary Following Radical Operation of Carcinoma of Uterine Cervix for Prevention of Symptoms of Abolished Function. A. Mandelstamm—p 1170

Hypophyseal Emaciation.—Stroebe calls attention to a group of women patients who are pale the musculature of the upper and lower extremities is atrophic and the subcutaneous layer of fat is almost completely absent. Cyanotic areas often appear on the hands and, after prolonged standing also on the lower extremities. The hair growth is often somewhat sparse. The appetite is impaired, and the patients complain of pains in the upper portion of the abdomen and of a dyspeptic pressure or of colic-like pains. The patients frequently complain of constipation. The systolic blood pressure as a rule, does not exceed 100 mm. of mercury. The author considers reduction in the basal metabolism and amenorrhea of primary importance in

this type of emaciation. This disorder is closely related to Simmonds' hypophyseal cachexia, in which there exists an atrophy of the hypophysis. The author thinks that in the disorder under consideration there is at least a functional disturbance in the hypophysis. He thinks it is advisable to administer hypophyseal preparations. Von Bergmann resorted to the implantation of hypophyseal tissue and obtained good results in four cases. Hypophyseal implantation has been done in seven cases and the menstrual flow was reestablished in two. Two hypophyses that had been taken fresh from calves were implanted into the omentum. Two months later, menstruation set in and since then had recurred every month. The patient's weight likewise increased following the implantation. The author's aim is not to recommend the implantation of hypophyseal tissue for all such cases but to emphasize the dominating influence of the hypophysis in cases of this nature.

The Myth of a Normal Cycle of Twenty-Eight Days—Holt declares that the regular cycle of twenty-eight days is largely a myth. He and a collaborator have kept exact records of the menstrual periods of several hundred women for several years, and so far they have not found a single woman who always had her menstruation exactly after the same length of time. He admits that he found some women in whom three, at the most four, successive cycles were of the same length, but if Ogino's demand is to be followed and at least twelve successive cycles are to be recorded it may be said that the woman with an unchangeable menstrual cycle is a myth. To talk of "normal cycles" or of "regular twenty-eight day cycles" is incorrect. There are thousands of women who assert that their menstruation occurs with unchangeable regularity, but, if exact records are kept over a period of a year or at least nine months, it will be impossible to find such a woman.

Do Pregnancy Toxicoses Result from an Allergic Condition? L. Seitz—p 1207
*Functional Interrelations Between Adrenal Cortex and Gonads S Thaddeus—p 1208
Problems of Sterilization. K. Holzapfel—p 1213

Treatment of Genital Hemorrhages with Radioactive Substances—Eymer's report is based on observations on 661 women with nonmalignant uterine hemorrhages, who in the years between 1913 and 1934 were treated with radium or mesothorium. The women were either myoma patients or had hemorrhagic metropathy. The latter condition existed in 412 women whose genitalia were otherwise normal. Since 1920, when the technic of the treatment was considerably improved, the author has observed only a small number of cases in which the treatment was a failure. In one woman, who was less than 45 years old, total extirpation was done when the hemorrhage recurred, while in another woman renewed radium irradiation produced complete cure. Slight hemorrhages recurred in four women. Radium treatment failed also in four women with myoma. Three were subsequently operated on, and in a fourth the radium treatment was followed by roentgen therapy. The author concedes that myomas are not always suited for treatment with radioactive substances. As a rule, only myomas that do not exceed twice the size of a fist are amenable to intra-uterine radium therapy. Moreover, in cases in which the uterine cavity is rather large and irregular on account of protruding myomas, radium treatment is inadvisable, as is the case also in submucous myomas. To the question whether intra-uterine radium irradiation should be preceded by curettage the author answers that it is advisable in most cases. However, curetting may be unnecessary in women with myoma in whom there is not the slightest suspicion of malignancy. Inflammations near the uterine cavity contraindicate intra-uterine radium therapy and, if inflammatory processes exist, the radium therapy must be postponed. The radioactive substance is enclosed in a brass container having a wall thickness of 1 mm. The author generally used from 50 to 60 mg of radioactive element. From 2,000 to 3,000 mg element hours is the usual dose for intra-uterine irradiations, that is, if 50 mg of element is used, it requires forty-eight hours to apply 2,400 mg element hours.

Following irradiation, a rose-colored or brownish discharge may persist for several weeks. After pointing out that radium therapy is superior to roentgen therapy in the treatment of nonmalignant uterine hemorrhages, the author stresses that for some women any form of intra-uterine irradiations is inadvisable and mentions women with hypertension and "younger" women, that is, those still capable of bearing children.

Interrelations Between Adrenal Cortex and Gonads—Thaddeus points out that experimental studies have produced evidence indicative of a modification of the gonads by the adrenal cortex. A stimulating effect on the ovaries has been observed. In children with hyperplasia or tumors of the adrenal cortex, sexual disturbances, such as pubertas praecox, premature menstruation, pseudohermaphroditism and hyperplasia of the genital organs, have been observed. In Addison's disease, on the other hand, there often exists gonadal hypoplasia or even complete atrophy of the ovaries and, as a manifestation of these morphologic changes, disturbances in the sexual cycle (irregular menstruations, oligomenorrhea and amenorrhea) frequently appear. Moreover, conception is rare in Addison's disease. However, in spite of these indications of a relationship between the adrenal cortex and the gonads, it is doubtful whether the adrenal cortex secretes a substance that acts directly on the female genitalia. It is more likely that the active principle of the adrenal cortex influences the gonads by way of the anterior lobe of the hypophysis. It is certain that the hypophysis, the regulator of the functions of the female genitalia, has relations to the adrenal cortex. In view of the close biologic interrelations between vitamins and hormones it must be assumed that the water soluble vitamin C has relations with the sexual sphere, as do the fat soluble vitamins. The author observed the extremely rare phenomenon of pregnancy in a woman with Addison's disease. In connection with this case he gave his attention to related problems: pigment formation, sodium chloride metabolism and adynamia. Clinical and experimental studies, conducted by him for the first time, disclosed radical changes in the carbohydrate metabolism in the pregnant woman who had Addison's disease and these changes furnish more information about the physiology and the functional pathology of the adrenal cortex.

Cesarean Section in Case of Fever During Birth—

Henkel thinks that in aseptic cases in which a cesarean operation becomes necessary the transperitoneal, cervical intervention is the best method. He discusses the problem whether abdominal cesarean section may be done also in cases in which fever has developed in the course of the delivery. He concedes that, when signs of an infection exist, it is desirable to attempt first an evacuation of the uterus by the vaginal route. However, it is inadvisable to force a vaginal method at any price. To perform the cesarean operation in spite of an existing infection is advisable in protracted deliveries in which the termination of the delivery by the vaginal route is impossible or difficult and likely to cause tissue lesions, which may exert an unfavorable effect on the infection. Since the cervical transperitoneal cesarean operation is best for noninfected patients, there is no reason to deny that it is not for infected ones. Porro's method of complete extirpation of the uterus which by some has been considered necessary for infected patients, the author regards as unnecessary in some cases. He gives a report of the eight cases of infection, in which he performed the abdominal cesarean operation. In three cases the uterus was extirpated (once on account of atonia), but in two other cases complete extirpation may not have been necessary. All eight patients recovered.

Treatment of Uterine Hemorrhages by Stimulating Mammary Glands—Cronental calls attention to Kellat's report about the successful treatment of uterine hemorrhages by the galvanic stimulation of the mammary glands. Then he describes the method that he employed in the treatment of uterine hemorrhages. He applies to the mammary gland, with the exclusion of the nipples, flannel cushions saturated with a 0.33% per cent solution of potassium iodide, over which lead plates are fixed and then connected with the cathode. The anode is connected with the electrode introduced into the vagina. The latter is a carbon electrode, the noninsulated end of which is covered with a cotton tampon saturated with an aqueous 1:1,000 solution of calcium chloride and covered with gauze. The strength of the current varies between 15 and 20 milliamperes. The treatments are given every second day or daily, each one lasting from twenty to thirty minutes. The author employed the treatment in 334 cases and obtained improvement in more than 86 per cent. The hemorrhages were of three types: (1) metrorrhagia caused by essential endometritis, (2) metrorrhagia in inflammatory processes and (3) metrorrhagia in patients with fibrous degeneration and fibromyomas of the uterus. In the future the author intends to replace the galvanic current in some of the cases by diathermy. Moreover, he found that the vaginal electrode may be replaced by an abdominal plate electrode.

Formic Acid in the Urine of Cancer Patients—Golber states that overloading with amino acids leads to an increase of formic acid in the urine. He refers to the unpublished work of Steppun in which the author expresses the idea that in the presence of lowered oxidation, such as occurs in cancer, a portion of the amino acids is split by hydrolysis with resulting formation of formic acid. Formic acid can likewise be formed in carbohydrate metabolism. Hydrolytic dissociation of lactic acid results in an acetic aldehyde and formic acid. Theoretically, because of deficient oxidation formic acid in the urine of patients suffering from a malignant tumor should be increased. The author investigated the formic acid content of a twenty-four hour output of urine from forty patients suffering from malignant conditions, twenty-six patients having other than malignant disease and eight normal adults. The formic acid content of the urine of healthy adults varied between 16.5 and 21.1 mg. and that of patients presenting other than malignant disease between 16.5 and 31.9 mg. Diabetic patients presented a much higher content from 59.8 to 139.1 mg. The formic acid content of urine from patients presenting a malignant condition varied between 34.7 and 101.6 mg. The author concludes that an abnormal amount of formic acid in the urine is characteristic of a malignant condition and may be used as a diagnostic test in such cases.

Transfusion of Preserved Blood—Karavanov reports 102 transfusions of preserved blood in seventy-three patients. The method of preservation consisted in adding to each hundred cubic centimeters of blood 100 cc. of physiologic solution of sodium chloride and 0.6 cc. of sodium citrate solution. The mixture was kept at a room temperature of 6°C. Destruction of red cells ran parallel with the number of days of conservation. The author considered from five to seven days the permissible limit of conservation. In six instances, blood was taken from various donors of the same group without provoking a reaction. Among the 102 transfusions there were noted fifty-six reactions, or 67 per cent. A strong reaction was noted in 26 per cent, average in 25 and weak in 16.4. The author concludes that transfusion of preserved blood merits wide application in clinical work. It should be particularly valuable in cases in which an immediate transfusion is required. He stresses the necessity of reexamining the blood just before the transfusion for sterility and hemolysis.

CRITICAL INTERPRETATION OF CLINICAL OBSERVATIONS

CHAIRMAN'S ADDRESS

A GRAEME MITCHELL, M.D.
CINCINNATI

Pearl¹ defines biometry as "that branch of science which studies by methods of exact measurement on the one hand, and precise and refined mathematical analysis on the other hand, the quantitative aspects of vital phenomena." There is certainly nothing new in a critical point of view in medical science, but too often it has led to nothing more than the negative result of skepticism. This is particularly true in clinical medicine, a growing percentage of whose practitioners are becoming conscious of the numerous modifying factors, often indeterminate, that influence living subjects. The essential attribute of living matter, as distinguished from so-called nonliving matter, consists in the relatively high variability of the former. One of the major divisions of the statistical method devotes itself to the measurement of variations, and no student of living matter should regard himself as properly equipped unless he has some knowledge of such technic. While it is a truism that chemistry and physics are exact sciences in that they deal with nonliving matter, nevertheless, as methods of measurement in these fields become more accurate and more sensitive, variability manifests itself more and more and makes the line of division between living and nonliving matter less and less distinct.

It has become axiomatic that medicine is an art as well as a science. Better, it might be stated that it is an art intelligently to apply scientific knowledge. There are still many procedures applied with the art which skill and experience bring but which can be reduced to the cold logic of figures. Contrary to the implication of the unfortunate and not even humorous story that there are liars, damned liars and statistics, figures do not lie—although, it is true, they may be made to deceive in the hands of those who do not know how to use them. It is quite true, as Pearl² states, that "it is not to be expected, or perhaps even desired, that every medical practitioner or investigator shall be an accomplished mathematician." Nevertheless, in the analysis of his observations and the presentation of his results, the author should use the proper methods that are available. Many earnest workers who would scorn to

use laboratory methods or instruments that have been long out of date still employ methods of analysis that render doubtful their conclusions or may even falsify them. The intelligent reader, too, must be aware of the terminology of statistical science and learn to think in its terms. One who would do nothing more than read the lucid first chapter of Pearl's book will at least gain an understanding of what the mathematician has to offer to clinical medicine. The judgment of the physician, which so largely determines the difference between doctors and good doctors, must always be a factor, since statistical analysis is concerned with groups and not individuals. All this does not countenance the continuation of incorrect procedures or uncertainty, or the passing on from one generation to another of impressions which are susceptible of proof or of denial.

It is obvious that the time at disposal allows only a plea for more general application of statistical methods in medicine, and the illustration of a few of the simplest examples of what it accomplishes.

REQUISITES OF STUDY

The first requisite of any study is an unbiased survey of the accuracy of the observations. One must see with a clear eye, palpate with a sensitive hand, listen with a sharp ear and note with an unprejudiced brain—avoiding by all means forcing the senses to interpret as the preformed conception dictates. It is easier, furthermore, to make rigid and pure one's own method of observation than to control the mental processes of others, and, in studies in which several investigators are involved, special attention must be directed at the so-called personal equation. The difficulties mentioned have led certain biometrists to discount many clinical observations. For example, I have heard it maintained that no physician can tell when a child is suffering from malnutrition. This is a silly assertion if meant literally. One does not need mathematical proof that malnutrition exists when it is marked, any more than one requires a thermometer to tell that water is hot when it burns one's skin. In borderline cases, however, the need for accurate analysis of clinical data is greatest.

One of the commonest errors of the unwary is the assumption that certain types of observation are worthy of record. Obviously it is futile and misleading to subject to critical study data that may be false. The point can be illustrated by referring to a subject that has often been mistreated, namely, the benefits derived from tonsillectomy.³ In many conditions the results of tonsillectomy are disappointing. Part, at least, of the unfulfilled expectations is due to the acceptance of unreliable statements from honest but mistaken sources, and to the failure to take modifying factors into

consideration Thus, while positive statements are frequently made concerning the beneficial effect of tonsillectomy on respiratory infections, it is not easy to prove that this association is direct cause and effect To accept this as *post hoc ergo propter hoc* fails to take into account such factors as the individual's inherent resistance, acquired immunity, exposure, other diseases of the respiratory tract, season, age, sex, hygienic conditions and the like Furthermore, how reliable is the casual statement of the mother or patient concerning the frequency and severity of respiratory infections over a period of years? How many physicians, without having made it a matter of special record, would be able accurately to state their own medical histories in such detail? Why, then, accept such statements on their face value from parents who obviously cannot give them accurately and who may be influenced by faith in the doctor or lack of it? How often, too, has the known influence of age on the incidence of rheumatic diseases been neglected in studies on the after-effect of tonsillectomy? One could cite such examples indefinitely Parenthetically, it should be stated that no attempt has been made here to prove that tonsil-

ture and standardization of which he is willing to delegate to others I can best illustrate by a few examples from actual experience with statistical analysis of clinical problems and a demonstration of some of these mathematical devices

In our studies of the influence of various conditions on specific skin reactions, my associates and I have noted the effect of several diseases on the skin reaction to tuberculin It has been frequently stated that measles might cause the tuberculin reaction to become negative The results of our own observations⁴ in measles and other diseases may be recorded as in table 1 The mathematical criterion employed in the analysis is that if the use of the formula $\frac{K}{PE_K}$ gives a result greater than 4 the result is significant, but that if it is less than 4 it is not significant In this particular case, K equals the difference between the rates⁵ of occurrence of positive reactions in the febrile and convalescent stages, and PE_K equals the probable error of this difference It can be seen from the table that it is fair to state that scarlet fever has a greater effect on the tuberculin reaction than measles, since the figure 10.88, derived from the use of the formula $\frac{K}{PE_K}$, indicates, according to mathematical calculation⁶ that the chances are about 70 billion to 1 that the difference between the rate of the skin reaction to tuberculin in the acute and convalescent stages is not due to chance, whereas in measles the figure 4.04, while still probably significant, indicates a mathematical probability of only about 140 to 1 that the difference is not due to chance alone Such a concept certainly conveys a much more accurate idea of the existing situation than does a simple percentage difference

A further advantage of statistical analysis is the ability to indicate the amount of material necessary to elicit significant results For example, the figure 1.83 (table 1) is the difference between the rates of the tuberculin reaction in the acute and convalescent stages of diphtheria divided by the probable error of that difference This cannot be accepted as significant, since such a difference would arise by chance alone approximately twenty-five times out of 100 without the operation of any causal factor—this not being regarded as statistically acceptable proof that it might not be a chance phenomenon However, the rates of reaction in both the acute and the convalescent stage of diphtheria are stable, i. e., in any given number of cases, tests made in the same way under the same conditions should give approximately the same rate In other words, from a statistical point of view it is not necessary to study this further, since multiplication of cases would not change the result A better illustration of the value of the statistical method in this respect is obtained in our observations on the effect of scarlet fever on the tuberculin reaction Several years ago we⁷ studied the tuberculin reaction during the acute and convalescent stages in 435 cases of this disease and

lectomy is without value, and the subject has been employed merely as a familiar illustration There must be mentioned the subject of "control" It is, in fact, the thoughtless assumption that a study has been properly controlled that has led to so many errors Workers in the laboratory are often faced with considerable uncertainty in regard to the adequacy of their controls, especially when living material is involved How much more skeptical should the investigator be when he is dealing with human material, in which endogenous and exogenous factors, often indeterminable, are legion

STATISTICAL ANALYSIS

Having reasonable assurance that the data to be studied are acceptable, what shall be done with them? Sometimes their meaning is more or less obvious, at others quite obscure Under the latter conditions one can turn to the devices of the statistician, many of which are available to the ordinary intelligence That is to say, a person need not be accomplished in advanced and intricate mathematics to become helpfully proficient in the use of certain formulas He need not necessarily have knowledge of the genesis or derivation of these devices but may accept and employ them on faith, much as he does laboratory instruments the manufac-

5 The term rate as used in biometry indicates the number of times a specific kind of event actually occurs divided by the times it might occur in the universe under consideration In this instance for example the rate of positive tuberculin reactions during the acute stage of scarlet fever was $\frac{35}{854} = 0.041$ To determine that a rate is stable it must when divided by its probable error give a figure greater than 4 In this instance the PE (probable error) was found to be ±0.007, so that 0.041 divided by 0.007 was 5.86 a significant figure which indicates that the rate was stable

6 Pearl Introduction to Medical Biometry and Statistics p 438 appendix III, table A

7 Eddy Bernice, and Mitchell A G Studies in Immunity Am J Dis Child 40 771 (Oct) 1930

found that 4 per cent of the patients had a positive reaction during the acute stage, whereas 19 per cent had a positive reaction during convalescence. If we had then applied statistical methods instead of amassing more figures, we would have found that the rates of the tuberculin reaction were stable during both the acute and the convalescent stage and that the rate was significantly higher in the convalescent stage. That is to say, the probability that the difference was not due to chance alone was about 500 million to 1. This is sufficient evidence that further study of this fact was hardly necessary, since the conventionally acceptable threshold is placed at odds of about 1,000 to 1.

The illustrations already given argue for the fact that the statistical treatment of data almost invariably leads to a clearer statement of the problem and cleaner and sharper attack on it. Too often, in clinical medicine, research consists of collecting a large amount of data and then attempting to find out what the data reveal—or conceal. The statistical technic would tend to reverse this process by first setting up the question and then indicating what data were essential to a final answer. It is of more than passing interest that the literature contains many papers demonstrating much labor in securing and gathering data from which incorrect conclusions have been drawn or in which the method of analysis is questionable. This section is not guiltless in its presentations, some of which have led to argument and discussion when statistical study would have obviated uncertainty.

The question is often asked "How many cases must be studied to answer a certain question?" A better way of stating this is "What should be the size of the sample from the 'universe'?" Investigators are almost always concerned with differences between experimental and control, and since studies on living material must of necessity be conducted on samples and never on an entire universe, there is always present the question of the sampling error or of variations arising because of the size of the sample. This is really an application of the probable error concept. The size of the sample depends on the question to be answered and the variability of the observations considered. It is evident that much work continues on matters that had previously been solved. Our own interest in the effect of scarlet fever antitoxin may illustrate this.⁸ For example, by observation of the effect of the administration of scarlet fever antitoxin on the incidence of complications in 112 patients and using as a control group in the same epidemic eighty-four patients, it was found that in the antitoxin-treated patients sixteen complications (14.6 per cent) developed, whereas forty-seven complications (56.1 per cent) developed in the patients who were not given antitoxin. Analyzing statistically by means of the chi-square test (which is a special application of the theory of probability) there remains no doubt of the significance of this difference in the two groups, since the figure 39.2 is obtained for chi square which indicates that the probability that the difference was not due to chance alone is over 500 million to 1. In the paper presented before this section last year by Lucchesi and Bowman⁹ figures were given on 3,045 patients treated by antitoxin and 2,332 patients who did not receive antitoxin. In the first group complications developed in 18.8 per cent, and in the second

group in 26.2 per cent. These figures suggest a difference in favor of the antitoxin-treated group but do not leave a flavor of finality. If the chi-square test had been applied, it could have been demonstrated that the probability that the difference was not due to chance alone was over 400 billion to 1 (chi square = 78.4). That is to say, the 196 cases that we had studied constituted a sufficient number to arrive at practically the same conclusions as the 5,377 cases of Lucchesi and Bowman. It may be stated, however, that the large number of cases presented by these workers demonstrated that it was only adenitis that could be proved to be influenced by antitoxin, and that our own series of cases was too small to permit study of the influence of antitoxin on individual complications. Any analysis such as has just been given, of course, does not consider such factors as severity, type of epidemic or age.

Statistical analysis can frequently decide on the value of clinical procedures and lead to the adoption of satisfactory technic. For example, in connection with studies on anemia in the Children's Hospital discussion arose concerning the relative accuracy of five different methods of counting erythrocytes. Only one factor—namely, dilution—need be discussed by way of illustration. If three different dilutions are made, 1:100, 1:200 and 1:500, of the same sample of heparin blood

TABLE 2.—Increase of Probable Error and Coefficient of Variability with Dilution

Dilution	Mean Red Blood Cells Million	Probable Error Million	Coefficient of Variability per Cent
1:100	3.439	±0.033	± 9.10
1:200	3.435	±0.040	±10.60
1:500	3.500	±0.074	±19.60

(other factors, as the type of pipet and counting chamber, the time and degree of shaking remaining the same) and the mean, the probable error and the coefficient of variability calculated for each dilution, it is found that, while the means are almost invariably within the limit of error, the probable error and the coefficient of variability increase very materially with dilution (table 2). Since this happens consistently with a large number of samples, even when different technicians perform the counts and provided the total count is not excessively high, the conclusion is clear that a dilution of 1:100 is more accurate from the standpoint of being subject to substantially less variability than a dilution of 1:200 or 1:500.

Time will not permit a discussion of several other frequently applicable statistical devices as correlation, the histogram, the polygon and curve fitting.

SUMMARY

The fact that clinical observations should be applied in the diagnosis and treatment of human ailments makes it essential that they shall be interpreted as correctly as possible. Statistical analysis should be employed to a much greater extent in clinical and laboratory investigation than is the case at present. The first requisite of any study is the assurance that the material to be analyzed is acceptable and that the control is really comparable. The operation of the law of chance can often be stated with precision rather than in the uncertainty of percentage comparison. Needless work and waste of time and material may often be avoided by statistical analysis. It should be emphasized that mathematical treatment relates in general to group

reactions and not to individual instances with which the clinician may be dealing and which may not follow the average but manifest peculiarities or represent extremes in the group. Statistical analysis does not obviate the necessity for thought and judgment.

Children's Hospital

THE SIMULATION OF INTRACRANIAL TUMOR BY LEAD ENCEPHALOPATHY IN CHILDREN

WITH REMARKS CONCERNING THE SURGICAL TREATMENT OF THE LATTER

PAUL C BUCY, MD
AND
DOUGLAS N BUCHANAN, MD
CHICAGO

Lead encephalopathy may present all the signs and symptoms of intracranial tumors in children. A group originally thought to be cases of intracranial neoplasm, but subsequently classified as examples of "serous arachnoiditis" because of the absence of any signs of tumor at operation, have recently been shown to be examples of intoxication with lead.

CASE 1—Roy C, aged 2 years, vomiting three months, two convulsions, staggering gait, large head, cracked pot sound, choked disks, hypo-active reflexes, glycosuria, separated cranial sutures, suboccipital decompression, no tumor found, demonstration of lead poisoning, lead line in roentgenograms, lead in blood, urine and feces, no anemia, lead line on gums or stippling of erythrocytes, complete recovery.

The patient who first drew our attention to the possibility that some of our cases of "pseudotumor" or "serous arachnoiditis" were really examples of lead encephalopathy was a small boy (Roy C), aged 2 years, who was referred to us by Dr. Joseph Brennemann of the Children's Memorial Hospital, Chicago.

History—Roy was admitted to the Bobs Roberts Hospital of the University of Chicago Clinics, Oct. 6, 1934. His parents stated that he had been a healthy child except for mumps at about 5 months of age, and a fall from his bed at 1 year, until three months prior to his admission. At that time he and his twin brother developed a diarrhea following the ingestion of some loose plaster from the kitchen wall. The twin was given castor oil, which he retained, and he soon recovered. The patient vomited the castor oil and also food taken that day. Subsequently he suffered from bouts of vomiting of increasing frequency. Six weeks prior to admission the patient had a convulsion, apparently tonic in character, which lasted about two minutes. Two days prior to admission he had a clonic convulsion which lasted for one and one-half hours. The parents had also observed that the child had become restless and irritable and that he frequently sucked his fingers. For a few days prior to admission the child seemed uncertain in walking and had fallen on several occasions.

Examination—Physical examination revealed that the child was well nourished. His head was large for his age and the superficial veins of the scalp were dilated. Percussion of the head, which distressed the child greatly, elicited a typical cracked pot sound (Macewen's sign). The child did not speak or seem to comprehend simple commands. He was able to walk, but only with his feet spread wide apart. However, he did not stagger or fall. On sitting up the patient had difficulty in maintaining his balance.

From the Division of Neurology and Neurosurgery of the University of Chicago Clinics.

Owing to lack of space, this article has been abbreviated for publication in THE JOURNAL. The complete article appears in the authors' reprints.

Read before the Section on Nervous and Mental Diseases at the Eighty-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., June 14, 1935.

There was a definite choking of both optic disks of from 2 to 2.5 diopters. No hemorrhages or exudates were seen in either fundus oculi. The pupils were round, equal and reacted rather slowly to light. Ocular movements were full in all directions, and there was no nystagmus. There was no other evidence of any involvement of the cranial nerves. No sensory loss could be detected. All extremities were abnormally flaccid but no localized weakness was present. All deep tendon reflexes were hypo-active. Babinski's sign was not present.

Urinalysis repeatedly revealed large quantities of a reducing substance in the urine. An examination of the blood (non-fasting) revealed 138 mg of dextrose per hundred cubic centimeters. A dextrose tolerance test was reported as normal. A blood count showed 13,800 white blood cells, 65 per cent polymorphonuclear leukocytes, 4,800,000 erythrocytes and 70 per cent hemoglobin.

Roentgenograms of the skull revealed definite, though moderate separation of all the cranial sutures (fig. 1).

A diagnosis of a midline tumor of the posterior cranial fossa was made, either a medulloblastoma of the vermis or an ependymoma of the fourth ventricle being suspected.

Operation—A suboccipital craniectomy was performed, October 11. Puncture of the left lateral ventricle through the occipital lobe revealed a dilated ventricular system containing clear colorless cerebrospinal fluid under considerably increased pressure. Both the cerebellum and the fourth ventricle, which were thoroughly exposed, appeared entirely normal. At the close of the operation a flanged needle was left in the left lateral ventricle in order to prevent a postoperative rise in intracranial pressure.

Postoperatively a diagnosis of "serous arachnoiditis," similar to that seen in the case of Esther S. (case 2), who had been operated on in 1931, was made.

Following the operation the patient's condition was very satisfactory. The ventricular needle drained profusely until removed two days after operation.

Demonstration of Lead Poisoning—Shortly following the operation it was suggested by Drs. E. S. James and D. Pachman of the pediatric resident staff that the patient might be suffering from lead poisoning. Immediate and repeated examinations failed to reveal any lead line on the gums or basophilic stippling of the red blood cells. Cerebrospinal fluid was repeatedly collected until 62 cc had been obtained. This contained 0.025 mg of lead. In 703 cc. of urine 0.100 mg of lead was found, and 106 Gm (wet weight) of feces contained 0.025 mg of lead. Blood drawn on October 24, and again on November 27, was submitted to Dr. Harold Blumberg of Johns Hopkins Hospital, who examined it spectrographically and reported 0.2 mg of lead per hundred cubic centimeters of blood in the first sample, which he stated "would indicate clinical lead poisoning or an early stage of convalescence from it," and 0.1 mg per hundred cubic centimeters in the second sample, which he considered evidence of "mild clinical or subclinical lead poisoning." In addition, Dr. Blumberg's examination revealed a slight argyria and subsequent inquiry revealed that the mother had frequently dropped mild silver protein in the patient's nose. Roentgenograms were made of the various long bones, and these revealed marked bands of increased density at the ends of the diaphyses (fig. 2).

Subsequent Course—The patient's condition rapidly improved. The choked disks soon subsided, fortunately without any optic atrophy. The cerebrospinal fluid pressure soon returned to normal.

Under the direction of Dr. Bengt Hamilton of the department of pediatrics, the child was given phosphorized cod liver oil in order to facilitate the removal of lead from active circulation and hasten its storage in the bones.² Under this treatment the dense bands at the ends of the bones rapidly widened (fig. 2). This increase in the density of the bands at the ends of the long bones may indicate increased calcium deposition as a result of the administration of phosphorized cod liver oil, the continued storage of lead or both.

The child was discharged, November 29, completely recovered from the lead encephalopathy.

² The utilization of phosphorized cod liver oil for this purpose is being experimentally investigated and will be the subject of a later report by Dr. Hamilton.

Family History—The family consisted of the mother (J C, aged 30) the father (Ralph C aged 34) and three brothers (Gilbert, aged 6, Wallace, aged 3½, and Ray the twin brother of the patient). The father's history was not significant. The mother had suffered from convulsions in infancy but had had no major illnesses since. All the children had had abnormal appetites and eaten many strange things including paint from the wall furniture toys and the like. Roy the patient, had been the greatest offender in this regard and while in the hospital had amply demonstrated this perverted appetite

Fig 1 (case 1)—Appearance of the skull Oct 8 1934. The coronal and parieto-occipital sutures are all markedly separated.

by chewing the tables and the arms of the chairs. Except for ingestion of plaster the history of the twin brother Ray is not significant. Both Gilbert and Wallace had each had three convulsions and each such attack was associated with vomiting. These however, had occurred months or years prior to Roy's illness. Roentgenograms of the wrists of the three brothers revealed nothing abnormal, so that these convulsions could not be definitely associated with lead intoxication.

Samples of the paint and plaster from the kitchen wall were shown to contain large quantities of lead.

There would seem to be little question as to the diagnosis of lead encephalopathy in this case. The history of the eating of plaster prior to the onset of the symptoms that led to the child's admission to the hospital was unwisely disregarded in making the diagnosis of cerebellar tumor. This history should have suggested the possibility of lead encephalopathy.

The occurrence of similar clinical pictures in cases of lead poisoning in children has been reported by McKhann³ and other observers. The absence of a lead line on the gums, anemia and stippling of the red blood cells in this case is not surprising, as their absence has been noted by others in cases of proved lead poisoning in children. The definite line of increased density at the ends of the bones in a child that had had no previous phosphorus administered, no viosterol and had apparently not suffered from rickets is very suggestive if not conclusive evidence of lead poisoning, while Dr Blumberg's demonstration of lead in the blood is definite proof. The absence of any considerable amount of lead in the urine or feces is readily explained by the fact that the child had been removed from his source of lead for a considerable period of time prior to the examination of the excreta.

³ McKhann C F. Lead Poisoning in Children. The Cerebral Manifestation. Arch Neurol & Psychiat 27: 294-304 (Feb) 1932.

That the convulsions from which the mother and two older boys suffered in infancy were due to lead intoxication cannot be proved, but the two boys were known to be afflicted with perverted appetites and there exists the possibility that the metal may have played some part in their cases. Ray, the twin was probably saved from more severe lead poisoning by the catharsis with castor oil as well as by the less marked pica which he showed in comparison with his brother Roy.

It will be recalled that at the time of operation we were impressed by the similarity between this case and other cases in this clinic which have been diagnosed as "serous arachnoiditis," particularly the case of Esther S. The histories and available roentgenograms of all such cases were reviewed and new roentgenograms of the long bones were made of all patients that could be located. In only one case, that of Esther S, were we able to establish a presumptive diagnosis of lead intoxication. Too long a period of time had elapsed in all cases to anticipate the demonstration of lead in the blood or excreta in any of these old cases and thus to establish a positive diagnosis. That it was impossible to establish the diagnosis of lead intoxication in the other cases of "serous arachnoiditis" which were mostly in

Fig 2 (case 1)—Appearance of wrist and knee. A left wrist October 17 showing definite bands of increased density at the lower ends of the radius and ulna and to a less extent at the peripheral ends of the phalanges. B, the same wrist two months later (December 10) after daily administration of phosphorized cod liver oil. The bands are more than twice as wide. children does not completely exclude that possibility as the reinvestigation was carried out several years after the acute episodes. The establishment of the proper diagnosis in the case of Esther S was largely dependent on fortuitous circumstances.

LEAD ENCEPHALOPATHY—BUCY AND BUCHANAN

JOUR. A. M. A.
JULY 27 1933

CASE 2—Esther S aged 5 years vomiting constipation and headache three weeks crossed eyes one week and stiffness of the neck, large head cracked pot sound choked disks of 4 diopters bilateral external rectus palsies flaccidity of extremities reduced reflexes positive Babinski meoordination walked on a wide base normal blood and urine, separation of cranial sutures, diagnosis midline cerebellar tumor no tumor found at operation serous arachnoiditis? complete recovery subsequent demonstration of lead line in long bones in original and later roentgenograms elicitation of history of pica

History—Esther S, aged 5 years referred to the University of Chicago Clinics by Dr Joseph Brennemann was admitted July 17, 1931 Her parents stated that she had been perfectly well until three weeks before admission at which time she began to vomit, at first only once or twice a day The vomiting became progressively more severe and frequent, until during the ten to fourteen days before admission she had been almost unable to retain any food or fluids The vomiting was not associated with nausea and the child complained of hunger At about the same time the bowels became severely constipated and evacuation by any means was very difficult

Fig 3 (case 2)—Appearance of the skull July 18 1931 The sagittal and parieto-occipital sutures are definitely separated Some digital markings are visible especially on the right

With the onset of the vomiting the patient began to complain of headache, which was present daily was variable in severity and was not localized One week before admission she began to complain of impaired vision and said everything looks funny About that time her mother noted that her eyes were crossed, the left being turned in Four days before admission stiffness of the back of the neck developed

Her birth, dietary and developmental histories were not abnormal She had suffered from measles at 17 months and scarlet fever at 2 years following which she had had an infection with discharge from the right ear

Examination—General physical examination revealed nothing abnormal On neurologic examination it was found that the head was enlarged and gave a cracked pot sound on percussion The optic disks presented a choking of 4 diopters There were many small hemorrhages over the disks a few in the retina and some patches of white exudate It was impossible to test the visual acuity or visual fields because of the lack of cooperation The pupils were round and equal and reacted normally There was a bilateral weakness of the external recti greater on the left There was definite flaccidity of all four extremities and distinct incoordination on the finger-to-nose test on the left The tendon reflexes were hypo-active,

the right knee jerk being more reduced than the left At times a bilateral Babinski sign could be elicited The child walked with her feet spread wide apart and with a staggering gait

Laboratory Examination—Urinalysis revealed no abnormality The blood examination showed 7800 white blood cells, 4700 000 red blood cells and 85 per cent hemoglobin The blood Wassermann and Kahn tests were negative, as were the intradermal tuberculin tests Roentgenograms of the skull were reported as showing only separation of the cranial sutures and digital impressions on the inner table of the skull (fig 3) A diagnosis of a midline cerebellar tumor (probably a medulloblastoma) was made

Operation—July 23 the patient was operated on by the usual suboccipital approach Puncture of the left lateral ventricle revealed a grossly dilated ventricular system containing clear colorless fluid under moderately increased pressure The cerebellum meninges, cisterna magna and fourth ventricle appeared normal The vermis was incised in the midline but no tumor was found The unsatisfactory diagnosis was made of acute internal hydrocephalus of unknown origin The patient made a rapid and uneventful postoperative recovery Following her discharge from the hospital the patient soon returned to normal activity There is at present no detectable evidence of any neurologic or mental impairment

Discovery of Lead Poisoning—After our experience in case 1 Esther was asked to return to the hospital for roentgenograms of the long bones The right knee and wrist were roentgenographed Oct 26 1934 (fig 4) The ends of the long bones as was to be expected were perfectly normal but in the shaft of the long bones there was a line of increased density about 1 mm in width This line was 37 cm above the lower epiphysal line in the femur 21 cm below the epiphysal line in the tibia and 19 cm above the epiphysal line in the radius The old films of the skull were then reviewed Fortunately in one corner of some of the films the head and upper end of the humerus was visible At the upper end of the diaphysis could be seen a very definite wide line of increased density, typical of lead lines' occurring in this location In addition, inquiry elicited from the parents a definite history of pica in this case although no specific instance of the ingestion of lead or lead containing substances could be recalled

Although the diagnosis of acute lead encephalopathy can never be positively established in this case, many things point to that as the correct interpretation

The history of the sudden onset of vomiting, constipation headache strabismus and stiffness of the neck with the finding of definite evidence of severely increased intracranial pressure and of no tumor at operation, the demonstration of lines of increased density in the metaphyses of the bones at the time of the acute illness and of similar lines at a considerable distance from the ends of the long bones after more than three years of growth and the elicitation of the definite history of pica preceding the acute illness make the diagnosis of acute lead encephalopathy as nearly certain as is possible after the elapsing of this period

Both of the preceding cases are also of great interest because of the rapid and apparently complete recovery following the making of a decompression

The third case presented a much less difficult diagnostic problem but is included, as it is the only other case of acute lead encephalopathy with sufficiently increased intracranial pressure to simulate a tumor that has been seen and recognized in the University of Chicago Clinics As the case was never seen by either of us, the record will be only briefly presented

CASE 3—Girl aged 6½ years admitted Oct 15 1930, attacks of epigastric pain for years one attack of jaundice and vomiting difficulty in walking bilateral foot drop absent ankle jerks slight blurring of optic disks anemia stippled

erythrocytes, diagnosis acute anterior poliomyelitis? or peripheral neuritis (lead)? Discharged October 27

Readmitted November 11, bilateral papilledema, right facial weakness, internal strabismus, separation of the cranial sutures, normal ventriculogram, large amount of lead in feces lead lines? in the bones, viosterol and calcium therapy, slow recovery

History—Betty, J. E., aged 6½ years, admitted to the University of Chicago Clinics, Oct 15, 1930, had for several years suffered from attacks of epigastric pain and severe anorexia. In the spring of 1928 she had been jaundiced and had vomited repeatedly. In August 1930, during an attack of whooping cough, she had vomited often and had no appetite. In September, difficulty in walking and slight aching pains in the thighs developed for which she was admitted to the hospital.

Examination—Physical examination in October 1930 revealed pallor, a systolic apical cardiac murmur and a distended bladder, which was readily evacuated. She had a bilateral foot drop and was unable to move her toes. The quadriceps extensors were also weak. The ankle jerks were absent. The right optic disk was slightly blurred.

The blood count revealed an anemia of 3,510,000 red blood cells, and smears showed marked basophilic stippling.

Discharge—The child was discharged, October 27. There was a difference of opinion as to whether the correct diagnosis was peripheral neuritis due to lead poisoning or acute anterior poliomyelitis.

Readmission—November 11 there was a bilateral papilledema of from 2 to 2.5 diopters, and the child was readmitted to the hospital.

Further inquiry elicited the fact that in April 1930 the patient had eaten an unknown quantity of white house paint.

Reexamination on November 11 and 15 revealed the foot drop and reflexes as before, a papilledema, a right facial weakness and a right external rectus paralysis. No lead line along the gums could be found. The blood showed an anemia and stippled red cells, which rapidly decreased in number, and none were found December 19.

Demonstration of Lead—December 6, Dr C. W. Muehlberger who had kindly examined the excreta, reported that 224 Gm of feces collected between November 13 and 16 contained 226 mg of lead.

Roentgenograms of the skull, taken November 13, revealed slight separation of the sutures and increased digital or "convolutional" markings on the inner table of the skull (fig 5). A ventriculogram was made November 17. The intracranial tension was greatly increased but the ventricular system was normal (fig 5). Roentgenograms had been taken of various parts of the body on October 17 and 22 and November 13, 17 and 29 and, except for those of the skull, were reported as normal. December 16, additional roentgenograms of the long bones were made. On reviewing the earlier films slight lines of increased density at the ends of the metaphyses were made out whereas those last taken showed definite and wider lines (fig 6). However, as large doses of viosterol and calcium lactate had been administered in the interval, the lines were not considered very significant.

Course—Following the ventriculogram the child was stuporous and later lethargic for more than two weeks and the papilledema was considerably increased. December 2 the choked disks were receding, but there was a bilateral external rectus paralysis complete on the right and partial on the left. Conjugate movement of the eyes upward was impossible. There was a right facial weakness. The foot drop was still present, but the ataxic gait was considered to be much more severe than it would explain. Slowly her condition improved and she was discharged, Jan 9 1931. The external rectus palsy had practically subsided. The optic disks and vision were normal. The foot drop was unchanged. She was last seen May 6. The foot drop was much better and her general condition was said to be good. Unfortunately, there is no statement as to her mental condition. Since then all track of her has been lost.

This child differs primarily from the others in that the initial symptoms were those of a peripheral neuritis. Not until several weeks later did signs of increased intracranial pressure develop, and this was much less severe than in the other two cases, in which headache and vomiting were pronounced symptoms and the lateral ventricles were grossly dilated. At no time was there any evidence of any localized intracranial lesion. The history of the ingestion of lead and the finding of a peripheral neuritis purely motor in type, an anemia, stippled red blood cells, and a large quantity of lead in the feces would seem to make the diagnosis of lead intoxication certain. In this particular case the roentgenograms of the long bones were of little or no diagnostic value.

Although there is no information concerning the child's present condition, her recovery would appear to be an unusually fortunate and exceptional one, particularly in that she recovered from a severe papilledema without developing an optic atrophy. In view of the rapid recovery in cases 1 and 2 as compared with the very slow recovery in this case, it would appear likely that this child would have been saved a long and severe illness by a decompression.

LITERATURE

Symptomatology—A clinical picture characterized by increased intracranial tension, choked disks, external rectus palsies, vomiting, headache and convulsions is particularly apt to occur in children as a result of lead intoxication. Although lead encephalopathy may occur in adults, it is not as common as in children and appears to be less commonly associated with sufficiently increased intracranial tension to be confused with brain tumor. However, that such is not always the case was pointed out as long ago as 1908 by Bramwell,⁴ who discussed the differentiation of the two conditions in adults. The differential points that he stressed were (1) evidence of lead poisoning such as a lead line on the gums, anemia, colic and wrist drop, (2) a history suggestive of previous lead poisoning, (3) occupation, (4) the character of the convul-

Fig 4 (case 2)—A portion of shoulder unintentionally included on the film of the skull taken on July 18 1931. A line of increased density is plainly visible at the upper end of the humerus. B same shoulder also included in a roentgenogram of the skull taken Jan 11 1932 six months after A. The line of increased density is now a short distance from the epiphyseal line indicating growth in the interim. C knee Oct 26 1934 more than three years after the acute illness. The lines of increased density are now several centimeters from the ends of the bones owing to growth during this time.

JOUR. A. M. A.
JULY 2, 1935

sions and peculiar mental conditions unlike those seen with tumors, and (5) the finding of lead in the urine. It is worthy of note here that Bramwell was dealing with and speaking of lead encephalopathy in adults. Unfortunately, in the main, his differential points are not applicable to children. As has been previously pointed out, evidence of lead poisoning such as the lead line on the gums, anemia, stippled red blood cells, and peripheral neuritis is commonly absent in lead poisoning in children. A history of previous lead poisoning is rarely elicited. Major convulsions are rare phenomena with tumors in the cerebellar fossa in children and their occurrence should make one hesitate before making such a diagnosis but in cases 2 and 3 it is seen that major convulsions may be absent in cases of lead encephalopathy. Changes of mentality in children are largely those due to increased intracranial pressure as is true in cases with tumors. The delirium, hallucinations and delusions so frequently seen in lead encephalopathy in adults are rarely observed in the child

Fig 5 (case 3) —Skull and ventriculogram Nov 17 1930. There is very slight separation of the coronal suture. The outline of the lateral ventricles which is just visible indicates a normal ventricular system.

That lead intoxication may result in signs of meningeal irritation or in generalized convulsions has been pointed out by Thomas and Blackfan,⁶ Blackfan-Strong⁷ and Holt.⁸ However, the paper by Suzuki and Kameko¹⁰ in 1924 describing the Japanese and Manchurian cases of 'serous meningitis' in infants arising from the use of lead-containing cosmetic powders by their mothers and the report by McKhann¹¹ in 1926 of cases of lead encephalopathy in children were the first really to direct attention to the prevalence and the seriousness of this condition in children.

McKhann's first patients suffered from vomiting, headache, stupor and convulsions. He drew attention

to the increased cerebrospinal fluid pressure but was not at that time impressed by changes in the optic disks. After further experience with the condition he published his paper of 1932¹² in which he pointed out that the majority of the symptoms—vomiting, visual disturbances, delirium, stupor, coma, convulsions, often elevated arterial pressure, choked optic disks and separation of the cranial sutures—were due to cerebral edema and increased intracranial pressure. This was a valuable contribution to the complete comprehension of lead encephalopathy in children and shifted attention from the toxic action of lead on the nervous parenchyma to the edema that results from damage to the mesenchymatous elements of the central nervous system such as the vascular system and the meninges. Other papers¹³ in association with Vogt in 1933 and 1934 reemphasized this point. Various writers, including Aub and his co-workers,¹⁴ confirmed the symptomatology as outlined and pointed out that the condition may simulate intracranial neoplasms, as did also Bailey.¹⁵

The most important recent diagnostic criterion that has been described in this condition in children is the presence of lines of increased density at the ends of the diaphyses of long bones which are visible with the x-rays. They were recognized and described by Park and his co-workers¹⁶ Caffey¹⁰ and Vogt.¹⁷ And though in the absence of other confirmatory evidence these lines would be interpreted by few observers as positive evidence of lead poisoning their presence is very suggestive of the possibility of lead intoxication. There is also the advantage that the existence of such lines of increased density can be easily and quickly determined.

Prognosis—The mortality from lead poisoning in children is extremely high. Blackfan⁷ states that of Stewart's seven patients with convulsions six died, and of his own four patients three died. Holt⁹ records that in thirty cases of lead poisoning collected from the literature there were twenty deaths. Aub and his associates¹³ state that the literature indicates a mortality of from 25 to 75 per cent in lead poisoning. McKhann and Vogt¹² state that in forty-five cases of lead encephalopathy in a Boston pediatric hospital there were eleven deaths (24.4 per cent).

Sequelae—Of equal importance with the mortality is the trail of physical wrecks that lead encephalopathy leaves in its wake. In the forty-five cases of lead encephalopathy recorded by McKhann and Vogt twelve (26.6 per cent) presented sequelae. These may take various forms. Gowers⁶ long ago pointed out the occurrence of a hemiplegia as a result of the disease. Aub and his associates, McKhann and Vogt, and others have reported convulsions, blindness, paralysis, speech deficiency, delirium and melancholia, tremor, anatomic changes and the like associated with such hydrocephalus. McKhann felt that the sequelae, like the acute signs, could be attributed to the increased intracranial pressure and edema with their attendant

impairment of the circulation. It should be pointed out that the anatomic changes in the blood vessels will contribute toward the same end.

COMMENT

Differential Diagnosis—The confusion of cases such as the ones reported here, particularly the first two, with cases of intracranial tumor is not surprising. The rapidity of onset, the early appearance of vomiting, the absence of definite neurologic changes other than those due to increased intracranial pressure, are typical of certain tumors occurring in the midline of the cerebellum of children. It is true that the majority of such cases usually present considerable uncertainty in walking, such as a staggering gait, but this may be minimal or absent, as case 3 reported by Cushing²⁶ in 1927 or case 24, reported by Bailey.²⁷ On the other hand, both cases 1 and 2 reported here presented a slight staggering gait and in case 3 the ataxia observed in walking was thought to be out of all proportion to the foot drop. Such staggering and incoordination in cases of lead encephalopathy may be due to the general debility of the patient or may be the result of degeneration of the large ganglion cells of the cerebellum reported both by Hassin¹⁹ and by Freifeld.²³ Flaccidity (hypotonia) of the extremities is common in midline cerebellar tumors but it was also present in these cases of lead encephalopathy. All the other usual signs of disturbance of cerebellar function (nystagmus, ataxia of the upper extremities and the like) are characteristically absent in cases of midline cerebellar tumors in children and thus are naturally of no value in differentiating these two conditions. It would seem that in many cases from a history and physical examination alone a differential diagnosis would be impossible. In those cases in which a blue line is present along the gums or in which there is an anemia and basophilic stippling of the erythrocytes, lead poisoning will of course be suggested to all observers, but unfortunately these signs are often absent in children. But in those cases in which there is a history of ingestion of lead or of substances that may contain lead, of a rapid onset with marked vomiting and abdominal pain, in which the signs of a localized intracranial lesion are vague or absent, the possibility of lead encephalopathy should be entertained. Such cases will usually show less elevation of the intracranial pressure as evidenced by a less marked separation of the cranial sutures than is usual in cases of cerebellar tumor. Whenever the possibility of lead encephalopathy is being considered in such a case, roentgenograms of the wrists and knees should be made to determine whether lines of increased density are present at the ends of the bones. In this connection it should always be borne in mind that the lead lines may be slight or absent as in case 3, for the lines indicate the deposition of lead in an inactive form in growing bones, not the presence of lead in a toxic form in the blood stream or brain, and either may be present without the other. It should be stressed that there are no positive criteria of lead encephalopathy in children and only constant vigilance and the use, when indicated, of all the diagnostic methods available will serve to establish the correct diag-

nosis. Fortunately, as will in a moment be pointed out, the error of diagnosing a case of lead encephalopathy as one of intracranial tumor does not seem to be fraught with grave danger if the proper therapeutic indications are followed.

Treatment—The therapeutic measures directed at the storage or removal of the lead itself have been very adequately dealt with by numerous recent authors.²⁸ That phase of the treatment will not be discussed here except to say that in our opinion "deleading" is not only an unnecessary but probably a dangerous procedure in children and should not be attempted except under the most unusual circumstances.

Numerous authors, particularly McKhann, have been impressed by the difficulty of relieving the increased intracranial tension by medical means. The convulsions can often be controlled by intramuscular magnesium sulphate or other methods, but the increased intracranial pressure, little or only temporarily affected by lumbar puncture and hypertonic solutions, continues unabated and results in death in at least one case out of every four and in sequelae in a like number. In less than 50 per cent of the patients under medical management can it be anticipated that they will survive their illness without bad effects.

Fig 6 (case 3)—Right ankle. A Oct 20 1930 a faint indefinite line of increased density is present at the end of the tibia. B December 16 after administration of viosterol and calcium lactate for two months the line of increased density is now distinct and definite. C Feb 16 1931 the line is still wider and more dense. It is of course questionable whether this can be spoken of as a lead line in view of the therapy.

The present report, limited as it is to three cases, would indicate that every case of lead encephalopathy with increased intracranial pressure should be given the benefit of a cerebellar decompression. The three cases reported here, though recovery occurred in all, are excellent illustrations of that point. Patients 1 and 2, both seriously ill, would have been given a bad prognosis under medical management. With a decompression both rapidly recovered, and in neither is there any trace of any sequel as a result of the illness, whereas in case 3, in which no decompression was made although the intracranial pressure was much less elevated, as shown by the slighter degree of separation of the sutures and the absence of any dilatation of the ventricular system, the recovery was very slow, for weeks the patient was stuporous, her condition growing worse, and for a long time her ultimate recovery

was actually in doubt. Surely if cases 1 and 2 are any indication at all her recovery would have been much more rapid with a decompression.

As to what form of decompression is most suitable, we have no information. In both of our cases a suboccipital (cerebellar) decompression was made. It has the advantage that the cerebellum is exposed in those cases in which the question of cerebellar tumor is not entirely settled, and it has the added value of leaving no unsightly scar or protrusion. It is obviously possible that a subtemporal decompression could prove as effective a mode of treatment. If so, it would have the advantage that it is a little more easily and quickly made but the disadvantage of the scar and of an obvious defect in the temporal bone. It is doubtful whether in competent hands the one is any more dangerous than the other in cases of lead encephalopathy.

SUMMARY

In two of three cases of lead encephalopathy in children with increased intracranial tension simulating cases of intracranial tumor, a suboccipital decompression was made. Both children recovered promptly and completely. In the third in which the intracranial pressure was less elevated no decompression was made and medical management alone was used. This child had a prolonged and stormy course but also ultimately recovered. From these experiences and from data taken from the literature it is concluded that

1 The differentiation of lead encephalopathy and midline cerebellar tumors in children from the history and physical signs alone is difficult and may be impossible.

2 Such factors as the possible ingestion of lead, rapid onset with vomiting and abdominal pain and only moderately increased intracranial pressure should warn the clinician of the possible diagnosis of lead encephalopathy.

3 The easiest and most rapid method of rendering probable the diagnosis of lead encephalopathy is the demonstration of the presence of lines of increased density at the ends of the long bones. The diagnosis may then be established by demonstrating the presence of lead in the blood.

4 Medical management of lead encephalopathy is notoriously unsatisfactory and results in a high mortality and numerous and serious sequelae.

5 Surgical decompression of the intracranial cavity offers a logical means of producing a prompt and complete relief of symptoms with less danger of sequelae.

ABSTRACT OF DISCUSSION

DR TRACY J. PUTNAM, Boston. The authors have called attention to an important point in the differential diagnosis. I have seen at the Boston Children's Hospital several patients with encephalitis due to lead poisoning whose symptoms closely simulated those of tumor. The differential diagnosis in such cases is one to which insufficient attention has been paid. In some of the cases at the Children's Hospital the intracranial pressure has been raised even more than I should judge was observed in the patients whose histories Drs. Bucy and Buchanan have reported. The sutures have been widely spread and the intracranial pressure as measured with a spinal manometer has been found to be over a 1000 mm. of water. A few of these patients have been operated on and decompression has been effected. In severe cases of increased suboccipital pressure decompression is apparently inadequate. I believe there are cases, however, in which benefit would be obtained by decompression. I am skeptical as to whether swelling of the

brain itself would be substantially reduced by suboccipital decompression, although this is strongly suggested in the cases of Drs. Bucy and Buchanan.

DR HANS REESE, Madison, Wis. Four years ago I examined a boy, 5 years of age who presented the characteristic signs of cerebellar tumor. I was not able to trace the syndrome to an intoxication or an infection and was not satisfied with the diagnosis of tumor, so I referred him to the neurologic department of the University of Chicago. Suboccipital decompression was performed but instead of a tumor, hemorrhagic arachnoiditis was found. Uneventful recovery followed this operation. The boy is alert, steady and quick, but an interesting feature is that within the last four years he has not grown. Clinical examination shows that he is normal and well nourished but undersized. His head is somewhat large but not hydrocephalic. After hearing this paper, I am of the opinion that in this case the possibility of encephalopathy due to lead poisoning was overlooked. I shall study the epiphyseal region to see if lead lines are evident.

DR ROY GRINKER, Chicago. Since attention has been drawn to the possibility of lead poisoning in the etiology of the rarely diagnosed cases of serous arachnoiditis, I have been impressed by the fact that the pathologic process in encephalopathy due to lead poisoning—changes in the ganglion cells, swelling of the brain meningeal proliferation and secondary hydrocephalus—are often found in children with a condition which Stone and I have called toxic encephalitis. These pathologic changes are so similar occur so frequently in children and lead to such similar sequelae that not only must evidence of lead poisoning be searched for as a possible etiologic factor in these cases in which a tumor is not present but in which simulating symptoms are noted and which have therefore frequently been called cases of pseudotumors but in addition one must be careful not to miss some previous acute infection that may have been responsible for the pathologic changes which later cause a rise in the intracranial pressure and thus confuse the clinical picture.

DR E. D. FRIEDMAN, New York. May I ask how the authors would explain the presence of the changes in the fundus noted in the last case?

DR L. H. LOESER, Newark, N. J. May I ask the authors to give further information as to the lead line in the bones? At what age does it appear? Is it present in adults?

DR PAUL C. BUCY, Chicago. The patient whom Dr. Reese mentioned is one in whom we were interested. However the roentgenograms taken at the clinic gave no clue as to whether or not it might have been a case of lead encephalopathy, and unfortunately we were unable to follow the patient further. I do not believe that the retardation of growth which occurred in Dr. Reese's case was due to the deposition of lead along the epiphyseal lines. As noted in case 2 such deposition does not retard growth. I am inclined to feel that the retardation of growth in his case was due to the intracranial changes produced by the disease. Although dilatation of the ventricular system is commonly associated with increased intracranial pressure its presence is by no means essential. It is well known that edema of the brain occurs in encephalopathy due to lead poisoning and I am inclined to believe that such edema is an adequate explanation of the papilledema and increased intracranial pressure that were noted in the third case. The lead line occurs only in children because it is associated with the laying down of calcium in growing bone. It is of no value as a diagnostic sign in adults.

Honored by Severe Criticisms—Bayle's contribution met with the greatest success that can come to any medical contribution in that it led to widespread consideration and discussion. In fact, the author was honored by many severe criticisms, not to mention personal attacks. As a result the question of chronic arachnitis became a lively issue in the medical world and from this original description of six cases and the conclusions drawn the subject has grown by addition to the present state of knowledge concerning dementia paralytica—Moore, Merrill, and Solomon, H. C. *Contributions of Haslam, Bayle and Esmarch and Jessen to the History of Neurosyphilis*, *Arch. Neurol. & Psychiat.* 32:804 (Oct.) 1934.

RECENT ADVANCES IN THE STUDY
OF INFLUENZATHOMAS FRANCIS JR, MD
NEW YORK

The name "influenza" usually conjures up a picture of the disease as it appeared during the pandemic of 1918-1919—a disease of widespread distribution and protean manifestations, characterized by rapid dissemination, a high frequency of complicating pneumonia, and a high mortality. In sharp contrast, one may present the milder epidemics that occur from year to year in different communities, usually limited in their scope, severity and complications. The number of cases that occur in these mild epidemics depends, to a certain extent, on the number of clinically similar infections that are included under the diagnosis of influenza.

THE DIAGNOSIS OF INFLUENZA

In fact, the lack of sharp differential features has rendered it difficult to separate influenza as a well defined clinical entity from many other mild infections of similar symptomatology that may invade a community. Thus the term "influenza" has been carelessly applied to various vague diseases of comparatively high morbidity which are associated with chills and generalized aches and pains and are of brief duration. A striking example of this tendency was reported from South America two years ago.¹ An epidemic of a mild nature, which was called influenza or grip, invaded a localized area in Brazil. When studies of the immunity reactions of individuals in this area were made, it was found that the disease was, in fact, yellow fever.

One may adopt, as requisites for the diagnosis of influenza certain criteria such as sudden onset with constitutional symptoms, chilliness, fever, myalgia, headache, mild respiratory symptoms without coryza, the presence of leukopenia and a course of from two to three days followed by considerable asthenia and exhaustion. These may serve as a working basis but are insufficient to exclude other entirely different diseases that exhibit a similar clinical picture.

Fig 1—Temperature chart of a ferret infected with human influenza virus.

THE PROBLEM OF
ETIOLOGY

A comparable state of uncertainty has prevailed in regard to the causative agent of influenza. Many different bacteria have been implicated, particularly *Haemophilus influenzae* and *Bacterium pneumosintes*,

but in no case has the evidence been sufficiently convincing to permit of their acceptance as the specific causative factors. Certain scattered data have previously been presented which suggest that the etiologic agent belongs to that group of ultramicroscopic infec-

tious agents called filtrable viruses. Although suggestive, the demonstration of a filtrable virus has not been conclusive, since repeated attempts by other workers to transmit the disease experimentally have yielded negative results.

RECENT STUDIES OF OTHER RESPIRATORY
DISEASES IN MAN AND ANIMALS

In recent years, however, three different series of studies have been carried on which have again increased the interest in the etiology of influenza. These three series of investigations have been concerned with diseases involving the respiratory tract which in each case has permitted of study of a disease occurring in its natural host.

The first of the series comprises the studies undertaken by Dochez,² Shibley, Kneeland and Mills, and Long and his co-workers³ on the common cold. Briefly, the results of the investigation indicate that the common cold in man is produced by a filtrable virus which can also initiate a similar condition in the chimpanzee, and that the virus can be grown

Fig 2—The lung of a ferret infected with human influenza virus, posterior aspect. Complete consolidation of left lower lobe.

in artificial mediums and after cultivation still maintains the capacity to induce common colds in human individuals.

The second study, carried out by Laidlaw and Dunkin,⁴ was concerned with dog distemper, a highly infectious respiratory disease. These investigators, in addition to their work with dogs, the natural hosts, succeeded in transferring the disease to ferrets and were enabled thereby to study the disease experimentally in a stock known to be free from natural infection and maintained under conditions of rigid quarantine. They were able to establish the fact that this malady is caused by a filtrable virus.

The third set of investigations is that of Shope,⁵ relating to a respiratory disease of swine, which, so far as is known, first made its appearance at the time

of the influenza pandemic of 1918-1919. This disease has been called swine influenza, or hog flu. It is characterized by fever, loss of appetite and weight, cough, respiratory distress and pulmonary consolidation, but it is of comparatively low mortality. Shope, in a series of brilliant studies, was able to demonstrate that the disease was produced and transmitted through contact infections by a filtrable virus in symbiosis with a bacterium of the group to which the human types of *Haemophilus influenzae* belong. The bacillus alone injected into the nose of a hog except in rare instances

Fig. 3—Lungs of mice infected with human influenza virus in comparison with normal mouse lung (N).

produced no effect, the filtrable virus alone produced a mild and, at times, unrecognizable infection but one which nevertheless was followed by a firm immunity against infection by the two agents combined. Furthermore, it was possible by the subcutaneous injection of the filtrable agent into swine to induce a state of immunity that protected against infection when the virus and influenza bacilli were injected together into the nose of the hog.

Studies such as these have served to heighten the probability that similar conditions may obtain in other epidemic respiratory infections, especially those of man.

TRANSMISSION TO FERRETS OF A FILTRABLE VIRUS FROM HUMAN INFLUENZA IN ENGLAND

In 1933 Smith, Andrewes and Laird⁶ instilled into the noses of ferrets filtered nasopharyngeal washings obtained from human patients during the acute stage of influenza. Two days after inoculation the ferrets became ill with fever, apathy, loss of appetite and nasal catarrh. The ferrets were killed on the third or fourth day after the onset of fever, and with emulsions of the nasal turbinate bones of such animals, these investigators were able to transmit the disease to other ferrets. The only pathologic change that they found in the infected animals was inflammation of the nasal mucous membranes. Ferrets that recovered from the disease were found to be immune to reinfection. The serum of these recovered animals contained antibodies that were capable of neutralizing the action of the infective agent when the serum and infectious material were mixed and then inoculated into a susceptible ferret. Similar antibodies were detected in the serum of men convalescent from influenza and in the serum of other human individuals as well. The active agent was found to be a filtrable virus and the addition of various bacteria caused no definite difference in the experimental disease.

EXPERIMENTAL SWINE INFLUENZA IN FERRETS

In addition, the British workers were able to transmit the virus of swine influenza to ferrets, producing a disease indistinguishable from that caused by the human strain of virus. Shope⁷ was able to confirm their observations regarding swine influenza in ferrets. Furthermore, he found that, when suspensions of finely ground lung of infected hogs or bacteria-free filtrates of such suspensions were injected intranasally into anesthetized ferrets, there developed, in addition to the inflammation of the nasal mucous membranes, involvement of the lung itself. The pulmonary involvement was of lobar distribution, firm and markedly edematous. The alveolar walls were thickened with many mononuclear and polymorphonuclear cells, while in the alveolar spaces the exudate was sparse and composed primarily of mononuclear cells. After repeated passages in ferrets the virus still retained its infectivity for swine, producing characteristic swine influenza when mixed with swine influenza bacilli, while in the experimental disease in ferrets no bacterial component was required. The serum of recovered swine or ferrets was found to be capable of inhibiting the activity of the virus.

RECOVERY OF A FILTRABLE VIRUS FROM HUMAN INFLUENZA IN AMERICA⁸

With the results of these studies as a background, during the winter of 1933-1934 I inoculated material from various human respiratory infections into the nasal passages of ferrets but, with the exception of one

Fig. 4—Low power magnification of consolidated lung of ferret infected with human influenza virus. Atelectasis and thickening of alveolar walls, edema fluid and scanty exudate in alveolar spaces. Early perivascular round cell infiltration.

instance of definite bacterial origin, I was unable to establish any disease in the animals.

In the early autumn of 1934, however, a widespread epidemic of influenza occurred in Puerto Rico. Through the kindness of physicians of the International Health Board, sputum was obtained from patients dur-

ing this epidemic. The sputum was placed in sealed bottles of 50 per cent glycerin packed in a vacuum jug with ice and shipped to New York by air mail. The materials were received from three to five days after collection. The sputum was washed free from glycerin and emulsified with Locke's solution, the emulsions were inoculated into the nasal passages of

Fig 5—High power magnification of same area shown in figure 4. The predominant cell in the exudate is a large pale staining mononuclear cell resembling the alveolar phagocytes.

ferrets lightly anesthetized with ether. On the second day after inoculation, fever developed in all the animals. Three days later one of these was killed and the lungs and turbinates were removed and ground in a mortar with sand and meat infusion broth. Part of the material was centrifugated and filtered through a Berkefeld V filter. Two ferrets were given the unfiltered suspension intranasally, another was given the bacteria-free filtrate by the same route. All three animals were taken sick and with the virus recovered from these animals it has been possible to transfer the disease in serial passages from ferret to ferret by means of suspensions of filtrates of either ground lung or turbinate.

In the first few passages of the virus through ferrets the disease is characterized by a diphasic type of fever and mild apathy, but little else (fig 1). After a few passages, however, in the lungs of ferrets that are killed on the fourth or fifth day, bluish consolidation of the lower lobes is usually noted and subsequently similar involvement of the lungs has almost always occurred after intranasal infection. In animals with pulmonary involvement the disease is more severe (fig 2). Their respirations are rapid somewhat jerky and labored, and at times moaning in character. A short dry cough may be noted. There may be a watery nasal and conjunctival discharge. The animals, usually alert and active are apathetic and lie quiet in their cages, eating little. After from five to six days, recovery begins and the animal rapidly regains an apparently normal interest in food and in its surroundings. Recovery is almost invariably the rule.

On the fourth day after the original material was obtained from Puerto Rico one of the laboratory assis-

stants was taken sick, and two days later another assistant was also taken sick both with symptoms typical of influenza. The throat washings obtained from these two patients at the height of the disease were inoculated into ferrets, and a characteristic experimental disease was produced. These observations indicate the infectiousness of the material for man, since influenza was not known to be prevalent in the community at that time.

THE EXPERIMENTAL DISEASE IN MICE

With filtrates of the sputum from Puerto Rico, and of the washings of the contact cases, attempts were made to establish the infection in mice, but without success. Different groups of mice, under ether anesthesia, were also inoculated intracerebrally, intranasally and intraperitoneally with filtrates of suspensions of lung from the different passage ferrets. We finally noted in one group of mice that were killed four days after intranasal inoculation, some small areas of reddish blue consolidation in the upper portions of the lungs. The involved areas were ground with sand and bouillon, and the centrifugated suspension was then injected into the nasal passages of other mice. By repeating this process through several passages in mice, it was finally possible with bacteria-free suspensions of the mouse lung, or with Berkefeld filtrates, consistently to induce this reaction in mice. The disease in mice, after intranasal infection is primarily one of the respiratory tract and essentially of the lungs. The rapidity of the course of the disease

Fig 6—Low power magnification of mouse lung at margin of consolidated area. In the upper part there is a great amount of edema fluid, partial atelectasis and early perivascular cuffing. The lower portion shows uninvolved lung with compensatory emphysema.

depends, to a certain extent, on the concentration of the infectious agent in the inoculum (fig 3). After the intranasal instillation of a 5 per cent suspension of lung tissue the mice begin to sicken on the second or third day; they are quieter, their coats become ruffled, and they huddle together and eat but little. The respirations become exaggerated, labored and audible; the eyes become wet and staring, and the animal dies in from four to eight days.

At autopsy, the lungs are almost completely involved. They are distended and a reddish blue, the surfaces are smooth and glistening and when the lungs are removed from the body considerable froth exudes from the trachea. In the earlier stages, the involvement is most marked in the dorsal aspects of the upper lobes and about the roots of the lobes. It has been possible to carry the disease through many transfers in mice, with only an occasional survivor. From the lungs of the mice one can in turn infect the ferret, producing a characteristic illness.

While these studies were in progress Andrewes, Laidlaw and Smith⁹ reported independently that they had been successful in establishing the human and swine influenza viruses in mice with a resulting pathologic picture similar to that which we have described.

MICROSCOPIC PATHOLOGIC CHANGES OF THE EXPERIMENTAL DISEASE

Microscopically, the changes in the lungs of both the ferrets and the mice are similar to those described by Shope⁷ in the lungs of swine and ferrets with swine influenza. There is a marked thickening and proliferation in the alveolar walls, there is an atelectatic appearance in some areas and the cellular exudate is comparatively scanty while considerable edema fluid may be present. The type of cell in contrast to that seen in the ordinary bacterial infections is primarily the large mononuclear and there is some infiltration of small round cells about the blood vessels (figs. 4, 5 and 6).

ADDITIONAL STUDIES

The results of filtration and cultural studies indicate that the infective agent of epidemic influenza is a filtrable virus. The infection has not been transmitted readily by contact from infected to normal animals or by other routes than the respiratory tract.

We have succeeded in recovering a similar infectious agent from the nasal washings of patients during the recent mild epidemics of influenza in New York and Philadelphia. The studies with these strains have not been carried out extensively as yet but the course of the experimental disease in ferrets and mice is much the same. The blood of patients suffering from influenza, in spite of the generalized symptoms has not been found to infect the mouse or the ferret nor has it been possible with the throat washings of patients to transfer the infection directly to mice.

SUMMARY AND CONCLUSIONS

The results of these studies, together with those of Andrewes, Laidlaw and Smith, have succeeded in establishing the fact that one, at least of the mild interepidemic diseases called influenza is causally related to a filtrable virus and can be transmitted experimentally to mice and ferrets. The disease in both species of animals chiefly involves the respiratory tract and produces a typical pulmonary consolidation. A human disease studied in two widely separate parts of the world and in each instance considered typical influenza, has thus been found to exhibit similar characteristics in experimental animals. The picture of the infection in the animals may serve not only as a guide for further investigations of influenza but also as a basis for differentiating influenza from other epidemic diseases which, at the present time, because of a lack of differential criteria, are probably included in the category of influenza.

AURICULAR FIBRILLATION IN HYPER THYROID PATIENTS

PRODUCED BY ACETYL- β -METHYLCHOLINE CHLORIDE,
WITH OBSERVATIONS ON THE ROLE OF THE
VAGUS AND SOME EXCITING AGENTS IN
THE GENESIS OF AURICULAR
FIBRILLATION

L. H. NAHUM, M.D.

AND

H. C. HOFF, Ph.D.

NEW HAVEN, CONN.

Auricular fibrillation is a serious cardiac irregularity which results from the onset of one or more circus movements in the auricular musculature (Lewis). The factors that initiate the circus movements are not too well understood. In the following study these factors have been investigated and it became clear that auricular fibrillation can be produced in hearts when they are subjected to the combined action of an exciting agent and overactivity of the vagus nerve.

THE ACTION OF THE VAGUS

Our first intimation of the nature of the physiologic mechanism involved in auricular fibrillation was obtained while observing the effects of acetyl- β methylcholine chloride on a hyperthyroid patient in whom a tachycardia had suddenly developed. As a matter of fact the patient was really suffering from auricular flutter, and administration of the drug converted the flutter into auricular fibrillation. The electrocardiogram obtained from this patient is reproduced in figure 1 and in the control record shows auricular flutter with a 2:1 block. After the injection of 50 mg. of acetyl- β methylcholine chloride the block gradually increased to 4:1, three minutes later the block was 5:1, the auricular complexes began to fragment and a coarse fibrillation was established and shortly replaced by fine auricular fibrillation. An hour and a half later when the effect of the injection might be expected to have worn off a normal slow supraventricular rhythm spontaneously reappeared (fig. 1 F). Figure 1 G is a reproduction of the electrocardiogram taken after a lapse of two days.

The increasing auriculoventricular block and the slowing of the ventricular rate are typical depressor effects and were to be expected from the well known action of the drug. The increase in the auricular rate from 316 to more than 600 was however, an entirely unexpected finding. It was obvious however that the vagus substance promoted the change from auricular flutter to auricular fibrillation.

The next logical step was to find out whether acetyl- β -methylcholine chloride might play a similar role in converting the normal heart mechanism in hyperthyroid patients into auricular fibrillation. Accordingly five patients at the Hospital of St. Raphael in New Haven were selected for study. Of these, one was doubtfully hyperthyroid, having a basal metabolic rate of plus 13. The other four were clearly defined hyperthyroid patients, with basal metabolic rates ranging from plus 26 to plus 48. All five received acetyl- β -methylcholine chloride in doses of 0.75 mg. per kilogram of body weight. Continuous electrocardiograms were taken in each case after the administration of the drug.

⁹ Andrewes, C. H., Laidlaw, P. P. and Smith, Wilson. Susceptibility of Mice to Viruses of Human and Swine Influenza. *Lancet* 2: 859 (Oct. 20) 1934.

From the Laboratory of Physiology, Yale University School of Medicine.

All five patients showed marked vagal as well as generalized parasympathetic effects similar to those described by Starr and his co-workers in man,¹ and by us in the infrahuman primates.² Accompanying these symptoms there was a rapid, and in two patients a profound drop in the blood pressure, requiring a subcutaneous injection of atropine sulphate, $\frac{1}{100}$ gram (0.0006 Gm.), to terminate the further action of the drug. In these two patients evidences of myocardial ischemia appeared and were recognized by a displacement of the ST segment of the ventricular complex (fig 2). In a series of similar studies made in a group of normal patients and animals, such a marked drop of the blood pressure was never observed with corresponding doses of the drug. Slowing of the heart rate and a partial auriculoventricular block took place in all five patients. Flushing was replaced at regular intervals of about four minutes by general peripheral vasoconstriction. These periods were found to coincide with transient increases in the heart rate. The maximum effects were reached from eight to ten minutes after injection and recovery was complete from forty-five minutes to two hours later.

Fig 1—Lead 2 in Mrs. S. aged 46 with a basal metabolic rate of +42. Auricular flutter for two days refractory to digitalis. Electrocardiograms taken at intervals of five minutes. A, control auricular flutter with 2:1 rhythm. B, five minutes after a subcutaneous injection of 50 mg. of acetyl- β -methylcholine chloride. C, 4:1 block. D, 6:1 block. E, beginning fragmentation of P waves. F, coarse auricular fibrillation. G, fine auricular fibrillation. G, resumption of normal rhythm one and one-half hours after injection of the drug.

In the four definitely hyperthyroid patients the drug also produced a short period of auricular fibrillation but

this was not observed in the doubtful case. Auricular fibrillation appeared as the effect of the drug approached a maximum while the normal mechanism reappeared from five to twenty minutes later (fig 3).

From these observations it became clear that the drug played a predominant role in the production of auricular fibrillation in hyperthyroid patients having normal cardiac mechanism. Since the acetylcholine

Fig 2—Lead 2 in Mrs. W. A, control. B, one minute after injection of 50 mg. of acetyl- β -methylcholine chloride, slowing of large S wave displacement of ST segment and inversion of the T wave. C, two minutes after injection. D, beginning recovery after injection of 0.01 Gm. of atropine.

derivative reproduces the same effects on the pacemaker and auricle of the heart as stimulation of the vagus nerves,³ it became clear that one factor in the spontaneous production of auricular fibrillation is the action of the vagus nerves on the heart.

Vagal excitation alone rarely causes auricular fibrillation. We have administered acetyl- β -methylcholine chloride to several normal individuals and to more than a hundred cats and monkeys and have never observed auricular fibrillation, nor was it reported by Starr and his co-workers in their studies on man. Eccles and Hoff³ observed a few extrasystoles at a rapid rate at the pacemaker following weak tetanic stimulation of the vagus of a cat but no true fibrillation, but, when Lewis, Drury and Iliescu⁴ added another factor such as faradic stimulation to the auricles of a dog during vagal stimulation, they observed incipient auricular fibrillation by faradic stimulation of the auricles alone. However, Eccles and Hoff have shown that in such instances local vagal ganglions are very likely to be stimulated even by very weak currents, in this way probably adding the vagal factor.

THE SECOND FACTOR

Thyroxine—The production of auricular fibrillation by the injection of acetyl- β -methylcholine chloride in the hyperthyroid patient and the failure to produce this disorder in the normal patient with the same or even

¹ Starr I. Jr., Elsom K. A., Reisinger J. A. and Richards A. V. Acetyl- β -Methylcholin Action on Normal Persons with a Note on Action of Ethyl Ether of β -Methylcholin. *Am. J. N. Sc.* 186: 313-323 (Sept.) 1933.

³ Eccles J. C. and Hoff H. E. The Rhythm of the Heart Beat. III. Disturbance of Rhythm Produced by Early Premature Beats. *Proc. Roy. Soc. Med. London* s. B 115: 352-368 (July) 1934.

⁴ Lewis Thomas Drury A. N. and Iliescu C. C. Further Observations upon the State of Rapid Reexcitation of the Auricles. *Heart* 8: 311-339 (Aug.) 1921.

larger doses of this drug makes it seem obvious that the excessive thyroxine present in the former case must in some manner account for the auricular fibrillation that is produced. Hearts under the influence of excessive amounts of thyroxine are stimulated so that they beat rapidly and also show increase in the rate of conduction and force of contraction⁵.

Thyroxine, therefore, might be considered an exciting agent on the heart. The widespread occurrence of auricular fibrillation in other than hyperthyroid persons indicates that agents other than thyroxine may operate with the vagus factor to induce and maintain this disorder. For purposes of exposition we propose to call this the E factor.

Electric Shock—The essential features of the effect of acetyl- β -methylcholine chloride on cats shocked electrically have been reported incidentally in a different connection² and may be stated briefly. In an animal given a preliminary injection of 10 mg per kilogram of acetyl- β -methylcholine chloride, electric shock with a 110 volt alternating current of short duration invariably produced auricular fibrillation. This condition lasts usually about from one and one-half to two hours, but with weaker shocks a normal rhythm returned in from fifteen to forty minutes.

Fig. 3—Lead 2 in Mrs. C. aged 32 weighing 53 Kg. with a basal metabolic rate of +48. Records at an interval of five minutes. A control. B five minutes after injection of 50 mg. of acetyl- β -methylcholine chloride. C partial block. D fragmentation of P wave and development of auricular fibrillation. E fully established auricular fibrillation. F transition back to normal rhythm. F fully established normal mechanism.

In most of our experiments the drug was administered first and the shock given from fifteen to twenty minutes later, but in some studies auricular fibrillation

was also produced by delivering the shock first and following it with acetyl- β -methylcholine chloride within a very few minutes (fig. 4).

It is apparent that electric shock, just as thyroxine, may, when combined with the vagus factor, produce auricular fibrillation.

Fig. 4—Lead 2 in cat weighing 2.5 Kg. under amylal anesthesia. A control. B, ten minutes after a subcutaneous injection of 25 mg. of acetyl- β -methylcholine chloride. C immediately after an electric shock from a 110 volt alternating current with a duration of two and one-half seconds. D resumption of normal rhythm an hour after C. Note the presence of Q wave in B and C and inversion of the T wave.

The disorder was of a temporary nature in the electrically shocked cats as well as in the hyperthyroid patients although of shorter duration in the latter. The hyperthyroid subjects either were able to antagonize the action of the vagus substance more readily or received a relatively smaller dose.

It is interesting to note that in our experiments auricular fibrillation developed without passing through the stage of flutter, nor did we observe flutter when the fibrillation passed away, although almost continuous electrocardiograms were made. Flutter therefore, is apparently not an essential intermediate stage in passing to or from fibrillation.

COMMENT

In these studies auricular fibrillation is shown to result when an increased quantity of the vagus substance acts on the heart in association with some other factor (E), such as electric shock or thyroxine. The degree of vagus activity is evidently of considerable importance since in the hyperthyroid patients the disorder occurred only when additional depressor effects produced by the injection of acetyl- β -methylcholine chloride were added to those already in existence. The spontaneous development of this disorder in hyperthyroid patients must therefore occur when increased depressor effects develop. Since many factors may lead to continued reflex cardiodepressor stimulation and since some individuals exist who are naturally vagosensitive,⁶ the necessary quantity of this factor may readily develop in the course of disease. How the

vagus contributes to the initiation of auricular fibrillation is not apparent from these studies. It is probable however that its chief function is to decrease the refractory period of the auricle thus permitting the initiation of circus movements.⁷

The manner in which the E factor thyroxine—or electric shock (in these studies)—acts in the production and maintenance of this disorder is also not completely clear at this time. The only factor in common between these agents is their property of exciting the myocardium.

Whether there exists a reciprocal relationship between the vagus and the E factor more of one requiring less of the other in order to induce auricular fibrillation cannot be answered from these experiments. It is interesting to note that in the ventricles a reciprocal relationship has been found to exist between electric shock and epinephrine.²

From the clinical point of view the spontaneous development of auricular fibrillation may now be explained by the simultaneous action on the heart of the vagus and an E factor.

In hyperthyroidism the overactivity of the vagus may develop reflexly from the tachycardia and growing hypertension so often found in these patients. Furthermore, we believe that increased sensitivity to the vagus substance naturally exists in such patients, for two of our subjects suffered severe reactions from normal doses of acetyl- β -methylcholine chloride and it is well known that hyperthyroid patients exhibit many parasympathetic symptoms such as sweating, flushing of the skin and gastro-intestinal hyperactivity. When the thyroxine effects on the heart reach a certain stage superimposed vagal overactivity will precipitate auricular fibrillation.

The proper combination of vagus and thyroxine may not and probably does not always exist. This is particularly true when the nerve effects are variable, in which case auricular fibrillation might occur in paroxysms a phenomenon very common in hyperthyroid patients and most frequent immediately after operation when large amounts of thyroxine are suddenly released into the blood stream.

Apart from hyperthyroidism auricular fibrillation is found to occur commonly in mitral stenosis, hypertension and congestive heart failure. In these conditions also the explanation for the disorder suggests itself. In mitral stenosis the distention of the auricle leads to an increase in the resting tension of the fibers which, as in skeletal muscle⁸ and nerve⁹ may appear in abnormal hyperexcitability. Stretch may therefore be an E factor in mitral stenosis. Active rheumatic infection might also serve as an E factor since de la Chappelle¹⁰ found a high incidence of active inflammation in the auricles of patients suffering from mitral stenosis in whom auricular fibrillation developed. At some stage of the disease should overactivity of the vagus develop or should the individual be abnormally vagosensitive¹¹ the correct combination of E factor and vagus overactivity should promote the development of auricular fibrillation.

In hypertension, vagal overactivity is probably a constant reflex phenomenon increasing in vagosensitive patients. When heart failure with auricular distention

and venous engorgement occurs, the stretch of the auricle may contribute the necessary stimulus (E) which when in association with vagus overactivity precipitates auricular fibrillation. It thus becomes clear why this irregularity is so often associated with heart failure, being rightly regarded as an important evidence of the existence of heart failure.

SUMMARY

Acetyl- β -methylcholine chloride converted the normal cardiac mechanism of four hyperthyroid patients and ten electrically stimulated cats into auricular fibrillation. In a patient with auricular flutter and 2:1 block the same substance converted the flutter into auricular fibrillation with a very slow ventricular rate. Auricular flutter did not appear in passing to or from fibrillation. The drug also altered the ventricular complex producing Q and S waves as well as displacements of the ST segments.

CONCLUSIONS

1. Auricular fibrillation is produced by the interaction of two factors on the auricular myocardium: (a) preponderant vagus activity and (b) an E factor such as thyroxine, electric shock or possibly simple auricular distention.

2. Acetyl- β -methylcholine chloride can rapidly convert auricular flutter into fibrillation and is thus a valuable agent for speedy slowing of the ventricular rate.¹¹

EVALUATION OF THE CONSTITUTIONAL EFFECTS OF LARGE DOSES OF ESTROGENIC PRINCIPLE

CHARLES MAZER, MD
DAVID R. MERANZE, MD
AND
S. LEON ISRAEL, MD
PHILADELPHIA

The present study was undertaken in an attempt to answer some of the questions propounded by the Council on Pharmacy and Chemistry of the American Medical Association in a recent report on the estrogenic substance theelin.¹ Without dwelling at length on the merits or demerits of the substance as a therapeutic agent, the report of the Council pertinently states: 'Evidence of deleterious effect from the clinical administration of estrogenic substance is not conclusive, but the possibility deserves serious consideration particularly if the large doses more recently employed clinically should come into common usage.' This study attempts to delineate the constitutional effects of huge doses of one of the estrogenic substances on the human female, as reflected in the ordinary laboratory and clinical studies at our disposal. This work is correlated with histologic studies of the vital organs of animals subjected to injections of enormous doses of the substance over periods varying from seven to fifty-seven days.

In the clinical study reported here only hydroxy-estrin benzoate in oil was employed, in the experimental

¹ Estrogenic Substances, Theelin. Report of the Council on Pharmacy and Chemistry, *J. A. M. A.* **100**: 1331 (April 29), 1933.

investigations on animals, dihydroxyestrin and, occasionally, theelin were injected. The three products were tested in our laboratory by the Allen-Doisy method and were found to contain the number of rat units herein indicated.

Hydroxyestrin benzoate,² 10,000 rat units per cubic centimeter

Dihydroxyestrin, 5,000 rat units per tablet (the tablets were dissolved in oil before injection)

Fig. 1—Section of rabbit liver before injection of dihydroxyestrin (from a photomicrograph with a magnification of 85 diameters)

Theelin in oil, 200 rat units (labeled 1,000 international units) per cubic centimeter

The clinical survey is limited to a group of twenty-nine adult women and one pubertal girl. These thirty patients, an integral part of a larger group treated with estrogenic substance, were sufficiently cooperative to permit completion of the studies. The indications for the administration of the estrogenic principle included amenorrhea, hypomenorrhea, dysmenorrhea, kraurosis vulvae, and the menopausal syndrome. An evaluation of the efficacy of estrogenic substances in the treatment of such disorders is not within the scope of the present discussion and is reserved for a forthcoming report, which will deal with the indications, dosage and limitations of estrogenic substance therapy. We may, however, state at this juncture that the severe menopausal syndrome and kraurosis vulvae are the two conditions requiring the use of the maximum doses employed in the treatment of these patients. The clinical observations and laboratory procedures were performed, in each instance, before and after the administration of estrogenic substance. The data recorded include body weight, blood pressure, basal metabolic rate, effect on the normal menstrual rhythm, complete blood chemistry (including sugar, urea nitrogen, uric acid, creatinine, cholesterol, calcium and chlorides), bleeding and coagulation times, urinalysis and complete blood counts (including differential study of leukocytes). In some instances, data of minor importance were not available for analysis because of the patient's lack of cooperation. Thus the hemoglobin values were completed (before and after treatment) in twenty-nine patients whereas the leukocyte and differential counts were available for

computation in only twenty-seven patients. The omitted data appear as blank spaces in the tables.

The dose of estrogenic substance administered varied with the indication and the individual's response to the therapy. The substance was given intramuscularly in every instance at intervals of four days. Fifteen of the thirty patients received 10,000 rat units per dose throughout the entire period of observation. The remaining number were given initially several doses of 10,000 rat units and subsequent doses of 5,000 or 2,000 rat units, depending on the patients' responses to the treatment. The total amount of estrogenic substance given to each patient was as follows: 260,000 rat units to one, 200,000 rat units to ten, 150,000 rat units to fifteen, and somewhat less than 100,000 rat units to only four. The period of treatment averaged three months. Only two patients were treated for six months.

No ill effects, either constitutional or local, were noted other than an occasional instance of local irritation. The latter was probably caused by failure to inject the oily solution intramuscularly.

EFFECT ON BASAL METABOLISM

The basal metabolism rate of twenty-two patients was recorded before and after administration of estrogenic substance. Only one, a well woman free of symptoms other than primary amenorrhea, showed a significant change, namely a fall from plus 26 per cent to minus 9 per cent. Since the patient manifested no hyperthyroid symptoms and since the fall in metabolic rate was to a figure within normal limits, no special significance may be attached to the change. It is noteworthy that another patient with a pretreatment rate of minus 30 per cent showed a final figure of minus 36 per

Fig. 2—Section of rabbit liver after injection of 150,000 rat units of dihydroxyestrin over a period of thirty days (from a photomicrograph with a magnification of 85 diameters)

cent. It seems that the administration of large doses of estrogenic substance has no demonstrable effect on the basal exchange.

EFFECT ON BODY WEIGHT

The body weight of each patient was observed at frequent intervals. No significant change was noted in the entire series. This is in accord with the observation of Kaufmann.³ The constancy of body weight during

² We are indebted to Drs. Gregory Stragnell and Erwin Schwenk of the Schering Corporation for the generous supply of progynon B (hydroxyestrin benzoate) and the dihydroxyestrin employed in the clinical and major part of the experimental work.

³ Kaufmann, C. Die Behandlung der Amenorrhoe mit hohen Dosen der Ovarialhormone. Klin. Wchnschr. 12: 1557 (Oct. 7) 1933.

prolonged administration of estrogenic substance was also noted in animals by Leiby⁴ and in our experimental work

EFFECT ON BLOOD PRESSURE

Twenty-six had normal blood pressures prior to the period of administration of estrogenic substance, three had systolic pressures of 140 mm of mercury, and one (patient 10), who had nephritis with hypertension, had an initial blood pressure of 170 systolic, 100 diastolic

Fig 3—Section of rabbit kidney before injection of dihydroxyestrin (from a photomicrograph with a magnification of 85 diameters)

No significant change occurred in the blood pressures of the twenty-six normal and the three slightly hypertensive women. Our clinical observation is in accord with the experimental studies of Laqueur⁵ and Melchionna,⁶ who found no blood pressure changes in animals after the administration of estrogenic substances. Liebhart,⁷ however, recently reported a moderate fall in the blood pressures of normal pubertal and mature females treated with relatively small doses of the hormone. The hypertension of our patient with nephritis remained unaffected throughout the period of treatment. This is in accord with the observation of Ayman,⁸ who failed to reduce arteriolar hypertension with moderate doses of estrogenic substance. We are at present treating by means of large doses of the substance a small group of women with essential hypertension and are, thus far, unable to corroborate the successful results of Fellner⁹ and Mayrhofer¹⁰

EFFECT ON COMPLETE BLOOD COUNT

The hemoglobin estimations (Sahl) and the erythrocyte counts showed no unusual changes following the use of estrogenic substance. In twenty-nine patients, the hemoglobin values remained within normal limits, anemia did not appear in any of them. The apparent relief of a marked secondary anemia in case 11 (table

1), during the administration of large amounts of the estrogenic substance, was probably the result of simultaneous administration of iron, arsenic and phosphorus. The erythrocyte counts remained constant and within normal limits. Our results concur with those of Hirst,^{11a} who administered estrogenic substances of varying amounts to new-born infants.

We found no appreciable change in the leukocyte counts of the twenty-seven patients following estrogenic substance treatment. Those patients who, prior to treatment had a slight leukocytosis (cases 7 and 22, table 1) showed approximately the same count at the termination of the injections. The differential counts were likewise practically unchanged in the group of twenty-seven. In his series of new-born infants, Hirst^{11a} found a relative decrease in polymorphonuclear leukocytes, a moderate rise in lymphocytes, and a tendency to eosinophilia after theelin administration. Ten of our patients did show an insignificant decrease in polymorphonuclear leukocytes and a corresponding rise in lymphocytes, six, on the other hand, showed exactly the reverse change, the remaining eleven patients presented no variation from the control counts. It is therefore illogical to ascribe any changes in the relative percentages of polymorphonuclear leukocytes and lymphocytes to the administration of estrogenic substances. The variations are within normal limits. A slight tendency to eosinophilia was, however, noted in three patients who had normal eosinophil values at the beginning of treatment and 4, 5 and 6 per cent, respectively, at the termination of the course of injections. Furthermore, eleven of the twenty-seven patients who had no eosinophils prior to administration of estrogenic substances showed normal percentages (1 to 3 per cent) following treatment.

Fig 4—Section of rabbit kidney after injection of 150 000 rat units of dihydroxyestrin over a period of thirty days (from a photomicrograph with a magnification of 85 diameters)

EFFECT ON BLEEDING AND COAGULATION TIMES

As shown in table 1, there were no deviations from normal in the bleeding times of the twenty-three patients examined. Thirteen of the twenty-four patients whose coagulation times were studied showed no variations from the normal, either before or after treatment.

Nine of this group, who had shown a tendency to prolonged blood coagulability (from seven to nine minutes) prior to treatment with estrogenic substance showed a moderate reduction (from one to three minutes) at the close of the treatment period. Hirst¹² found that the aqueous solution of progynon, unlike theelin, increases the coagulation time of new-born infants. The fact is

Fig 5—Section of rabbit adrenal before injection of dihydroxyestrin (from a photomicrograph with a magnification of 85 diameters)

that the aqueous solution of the estrus-inducing hormone, dispensed under the name of progynon is a mixture of theelin and theelol and therefore should not differ in its effect on coagulation time from that of theelin.

One may conclude that healthy adult females show no significant change either in coagulation or in bleeding time with massive doses of estrogenic substance. The reduction observed in the coagulation time in the nine patients who showed somewhat high values prior to treatment is in accord with the observations of Hirst¹² on new-born infants. He states: 'Abnormally long coagulation and bleeding times as well as spontaneous bleeding other than vaginal were corrected by injections of theelin.' By inference one may assume that the hormone has some beneficial influence on the course of hemophilia—an effect attributed to the estrogenic substance by Birch¹².

EFFECT ON BLOOD CHEMISTRY

Following the administration of estrogenic substance, no striking variations were noted in the chemical constituents of the blood, as measured by the ordinary laboratory means (table 2). The values were unchanged whether or not the initial study showed very high or very low figures.

The unchanged serum calcium determinations concur with those of Dixon,¹³ Frei and Emmerson¹⁴ and others in blood studies on animals. The constancy of the cholesterol values is of unusual interest in view of the close chemical relationship between the estrus-inducing hormone and cholesterol. In case 28 a low cholesterol content changed to a normal level following the treatment; in case 19 the reverse occurred (table 2). No

importance need be attached to these fluctuations, since neither of the patients showed any evidence of thyroid dysfunction.

Though the blood sugar levels of normal women remain unaffected with the use of large doses of the estrogenic substance, the blood and urine of diabetic women show an appreciable decrease in the sugar content during injections of the product. This observation is limited to only three patients, two of whom received 400 rat units of the estrogenic substance daily and one of whom received 10,000 rat units every fourth day for a period of from four to six weeks. The maximum fall in blood sugar observed in these three diabetic patients was 60 mg. There was in each instance, a return to the former level soon after withdrawal of the treatment. This clinical observation is in accord with observations of Barnes¹⁵ on the blood sugar levels of pancreatectomized dogs injected daily with 200 rat units of aminotin (one of the commercial products of the estrogenic hormone). Theoretically, the fall in blood sugar of the experimental animal following injections of the estrogenic substance is caused by inhibition of the diabetogenic function of the anterior pituitary lobe, since hypophysectomy in the pancreatectomized dog produces the same results.

EFFECT ON KIDNEY FUNCTION (URINALYSIS)

Repeated examinations revealed no albumin or casts in the urine of the twenty-nine normal women. Nor did we find any increase in the number of casts and quantity of albumin in the urine of the one nephritic patient (number 10) as a result of the administration of 120,000 rat units of the estrogenic principle given over a period of five weeks. The finer tests for kidney function other than blood chemistry determinations were not performed.

Fig 6—Section of rabbit adrenal after injection of 150,000 rat units of dihydroxyestrin over a period of thirty days (from a photomicrograph with a magnification of 85 diameters)

EFFECT ON MENSTRUAL RHYTHM

The effects produced by estrogenic substances on abnormal types of menstruation is not within the scope of this report. They will be considered in detail at a later date. However, the effect of the hormone on the regular menstrual cycle is germane to the subject under discussion. We noted the menstrual cycles of seventeen

regularly menstruating women treated with the large doses of estrogenic substance because of hypomenorrhea, dysmenorrhea, adenosis of the breasts and the like. Only five of the seventeen are included in the present series of thirty patients (cases 4, 5, 6, 15 and 16 in tables 1 and 2)

reported intermenstrual staining of from one to two days' duration while receiving treatment. All of the six patients who showed disturbed menstrual rhythm as a result of the treatment with estrogenic substance continued to menstruate regularly during a follow-up period of nearly a year.

Eleven of the seventeen patients showed no changes in the menstrual rhythm either during or after administration of estrogenic substance. Six patients experienced a single delay in the appearance of the menstrual flow varying from one to three weeks during the course of three months' treatment with large doses of estrogenic substance. Four of these six patients as well as one of the eleven who had no disturbed rhythm

illustrative of the nature of the temporary disturbance in menstrual rhythm is the protocol of one of the patients, shown in table 3. The establishment of a new date of onset of the subsequent menses following a short delay in the flow in six of the group may, in the light of present limited knowledge of sex physiology, be attributed to a temporary inhibition of the gonad-stimulating function of the anterior pituitary lobe.

which the estrogenic hormone is known to produce in the experimental animal (Leonard and his associates,¹⁶ Moore and Price¹⁷ and others)

The deleterious effects of large doses of estrogenic substances on the human ovary are conjectural. The presence of a high content of estrogenic substance of the blood during pregnancy militates against this possibility. Experimentally, Allen¹⁸ and Katzman¹⁹ have shown that the pituitary inhibition resulting from the administration of estrogenic substance is only slightly reflected on the ovarian structures of adult rodents, unless huge amounts are administered. Hohlweg,²⁰ for instance, maintains that daily injections of 100 rat units of crystalline dihydroxyestrin over a period of thirty days stimulate hyperluteinization in adult rats. Be that as it may, it seems that large doses do disturb the menstrual rhythm of regularly menstruating women, at least temporarily.

The effect of intensive treatment with estrogenic substances on the fertility of the human female is difficult to ascertain from a study of a small group of patients. Most of our seventeen regularly menstruating women are sterile for various reasons. None have as yet conceived. One of Clauberg's²¹ patients conceived shortly after the administration of 400,000 mouse units

deficiencies of the estrus-inducing factor. In this type of patient, one would not expect any increase in libido from treatment with estrogenic substance. That an increase of libido does occur in castrated women during treatment with estrogenic substance was reported by Werner and Collier²² and was likewise observed by some of our patients. The pathologic increase in libido following estrogenic substance therapy, as postulated by Poate,²³ is, we believe, restricted to the small group of patients who already have a high estrogenic content of the blood. We have found this to be true by repeated blood hormone titrations in three highly neurotic women suffering from nymphomania.

EXPERIMENTAL OBSERVATIONS

As a corollary to our clinical studies, we subjected thirty immature and adult rabbits to daily injections of enormous doses of the estrogenic substance over periods varying from seven to fifty-seven days. They received, individually, total amounts varying from 80,000 to 150,000 rat units—quantities relatively far in excess to those given our patients. Nevertheless, none of the vital organs (liver, kidneys, heart, lungs and adrenal bodies) showed either macroscopic or microscopic evidence of pathologic changes, as shown in the photomicrographs. Description of the changes in the pituitary gland, breasts, ovaries, fallopian tubes and uterus will be given in another communication dealing mainly with the endocrine response of the experimental animal to such large doses. We may state at present, however, that the response of the endocrine glands (stimulative or regressive) varies with the age of the animal, the dose, the length of the treatment and, above all, the species susceptibility of the animal to the estrogenic substance.

Experimental observations cannot, therefore, be translated accurately into human equations. We must await further clinical reports of a reliable nature before we render an opinion on the nature of endocrine response of the human being to large doses of the estrogenic substance. From a careful survey of our clinical material, only part of which is herein reported, we are inclined to believe that doses within the limits mentioned are harmless after the child-bearing age and in younger women who no longer desire offspring.

SUMMARY

From a survey of the literature and the clinical study of thirty patients, it was found that injections of from 100,000 to 200,000 rat units of estrogenic substance, given in divided doses over periods of from two to three months, produce no appreciable changes in body weight, basal metabolism, blood pressure, blood count, coagulation and bleeding times, blood chemistry and urine.

In six of seventeen regularly menstruating women, injections of these large quantities of estrogenic substance produced a temporary delay in the menstrual flow (from one to three weeks) and established in these six patients a new date of onset of the menses. This phenomenon is apparently due to a temporary inhibition of the anterior pituitary lobe which normally controls ovarian function. The effect on fertility is, as yet, unknown.

Growth of the mammary glands and increased libido were observed in a few of the treated patients.

TABLE 3—*Nature of the Delay and the Establishment of a New Date of Onset of the Menstrual Flow Incident to Intensive Administration of Estrogenic Substance*

White woman, aged 26 Menarche at 14 years, regular 31-day cycle Chief complaint: dysmenorrhea Menses: January 1	
February 2	February 10
March 5	Hormone treatment
April 18 (delay of 10 days)	
May 10	
June 20	
July 21	June 1

(80,000 rat units) of estrogenic substance. Two of our sterile patients (not included in this study) conceived shortly after the administration of 22,000 and 18,000 rat units, respectively. Experimentally, Katzman¹⁹ found no reduction in fertility of adult rats following the administration of relatively large amounts of estrogenic substance.

EFFECT ON NORMAL BREASTS

Only a few of the group of women treated showed evident growth of the mammary glands. This phenomenon is more marked in some children who are treated with relatively large doses of estrogenic substances for gonorrheal vaginitis. The growth is temporary, receding rapidly after withdrawal of the substance.

EFFECT ON LIBIDO

Absence of libido is more often caused by psychic factors and abnormal marital relationships than by

Relatively larger doses of the estrogenic substance (from 80,000 to 150,000 rat units) than those employed clinically produced neither macroscopic nor microscopic changes in the vital organs of thirty rabbits. The response of the ovaries to huge doses of the estrogenic substance is either degenerative or stimulative, depending on the species and age of the test animals and the duration of administration of the substance.

HEART DISEASE IN THE CHICAGO AREA

A STUDY OF THE ETIOLOGIC FACTORS IN ONE THOUSAND CASES

CHAUNCEY C MAHER, MD
WALTER W SITTler, MD
AND
RALPH A ELLIOTT, MD
CHICAGO

Since the publication of the Criteria for the Classification and Diagnosis of Heart Disease,¹ sponsored by the American Heart Association, and the pioneer work of White² and Wyckoff,³ increased interest has been manifested in studying the etiologic factors operative in the production of heart disease. Authorities are agreed that the incidence of heart disease is increasing each year. Perhaps the pertinent point in stemming this increase may be elucidated through an examination of the causative factors.

The value of the work of the committee that has advocated the publication of the Criteria for the Classification and Diagnosis of Heart Disease in directing current thought toward the consideration of heart disease from the etiologic, anatomic and physiologic points of view is becoming more and more obvious. The standards set forth by this committee merit adoption by all hospitals and cardiologists, thus permitting uniform reports of the incidence and type of heart disease throughout the United States. The Middle West was negligent in reporting any statistical data until Flaxman's report⁴ appeared from the Cook County Hospital.

We here present our studies of 1,000 consecutive cases of heart disease encountered in private and consultation practice in the Chicago area. Both hospital and office patients are included, although the majority were ambulatory. With three exceptions, they were all of the white race, two were Negroes and one was Japanese. All ages are included, but adults preponderate over children.

A problem that confronts an author in presenting such material statistically is the frequency of more than one etiologic factor in the same individual. For example, a patient may have both hypertensive vascular disease and syphilis. The pulmonary heart (cor pulmonale) case may also show hypertension, arteriosclerosis or syphilis. Thyrotoxicosis may be compli-

cated by rheumatic infection or hypertension. A number of complicating problems of this sort might be cited.

In some of the statistical reports of the etiologic factors of heart disease, the percentages are computed by counting the total number of etiologic factors and then calculating the percentage of any given factor from this sum rather than from the total number of patients. It is our belief that this method gives somewhat an incorrect concept of the actual facts. We have been unable to devise any absolutely satisfactory method of presenting our data which takes into consideration the multiplicity of etiologic factors in single cases and still presents a true picture of the percentage basis from the total number of cases involved. Our final conclusion on this problem was to consider twelve main groups, as follows:

- 1 Rheumatic infection.
- 2 Hypertension.
- 3 Arteriosclerosis
- 4 Syphilis
- 5 Thyroid disease.
- 6 Pulmonary diseases
- 7 Congenital causes
- 8 Neurologic causes
- 9 Toxic causes
- 10 Traumatic causes
- 11 Bacterial entities
- 12 Unknown or unclassified causes

Our material will be presented under these twelve headings and subclassification made in each of these groups to demonstrate the interrelationship of the various factors.

Chart 1 is a diagrammatic representation of the number of cases in each general group. The shaded area of each block represents the number of cases complicated by secondary etiologic factors. The distribution of these secondary complications is further discussed under the separate headings. Rheumatic infection, hypertension and arteriosclerosis are overwhelmingly in preponderance. Syphilis, thyrotoxicosis and pulmonary disease are next in frequency. Bacterial, congenital, toxic and traumatic factors rank least. Functional heart disease was encountered in eighty cases, or 8 per cent, of the total. Eighty-four cases were unclassified or the etiologic factor was unknown.

RHEUMATIC HEART DISEASE

The criteria for the establishment of rheumatic heart disease were those described in the Criteria for the Classification and Diagnosis of Heart Disease,¹ which are as follows:

- 1 History of polyarthritis, chorea, muscle or joint pains, of subcutaneous nodules, and evidences of a characteristic structural lesion of the heart.
- 2 Evidence of a characteristic structural lesion plus a history of periods of recurrent fever and cardiac insufficiency.
- 3 Evidence of carditis of the type associated with active rheumatic heart disease even in the absence of other rheumatic manifestations.

Rheumatic heart disease was present in 292 cases. Of these, 22.2 per cent, or sixty-five cases, were complicated by secondary factors, as demonstrated in chart 2. Occasionally there were as many as three etiologic factors present in a single case.

The most common complicating factor was thyrotoxicosis, occurring in 9.5 per cent, or twenty-eight

HYPERTENSION

The criteria for the diagnosis of heart disease due to hypertension as given in the Criteria for the Classification and Diagnosis of Heart Disease are as follows "Persistent hypertension associated with enlargement of the heart" The frequent association of arteriosclerosis is discussed In this study these standards were followed The most difficult problem was to arrive at a reasonably accurate decision concerning the significance of associated arteriosclerosis In general we have added arteriosclerosis as an associated factor in patients in whom there was a well marked peripheral arteriosclerosis or who presented clinical evidence of coronary, retinal or cerebral arteriosclerosis There is no doubt that our figures are inaccurate in this respect Decision has been a personal estimate of degree If one were to follow all the hypertensive cases from beginning to end, the frequency of an associated arteriosclerosis would undoubtedly be much higher

Two hundred and sixty-two patients were classified in the hypertensive vascular group, representing an incidence of 26.2 per cent of the total Chart 3 is a diagram showing the comparative frequency of the other etiologic factors associated with hypertension One third, or eighty-nine cases, were classified as having an associated arteriosclerosis Almost one tenth, or twenty-five cases were thyrotoxic Eleven cases were also classified in the rheumatic group Nine of our cases were classified as having pulmonary disease We are inclined to believe that this figure is too low In our early records, there is no doubt that we paid too little attention to pulmonary factors, and it is our impression that pulmonary disease is much more often a complicating factor in this group than our figures would indicate There were only four cases in which syphilis was associated

Chart 3—Demonstration of the combination of hypertensive vascular disease and other etiologic factors

Comparison may be made of our figures with those of Flaxman, who records an incidence of hypertension of 43 per cent in his studies to our figure of 26.2 per cent Again the difference is due to the material studied and to the fact that the indigent hospital group contained 28 per cent of the Negro race The incidence in New England, as reported by White,⁹ was 29.2 per cent The incidence of hypertension in other statistical reports appears to be greatest in the South where figures range from 47 per cent to 68 per cent¹² and least in the Rocky Mountain region, where Viko¹¹ reported only 14.9 per cent

In view of the fact that the majority of our patients are in the age group of 40 years or above, systemic disease of many types has been frequently tabulated as a complication in the study of this hypertensive vascular group The nephritic cases have been included in this group when associated with hypertension

In studying our older records, it appears that insufficient attention has been paid to urologic disease The

Chart 4—Demonstration of arteriosclerotic heart disease and other etiologic factors

urologic pathologic condition has been brought to our attention in cases that have been under observation for some years and in which acute problems have developed, such as cystitis, renal colic, hematuria or pyuria In the male, asymptomatic prostatism, old stricture and chronic urethral and prostatic infection were readily overlooked In the female, bladder deformities, pyelitis and hydronephrosis were overshadowed by more obvious cardiac symptomatology The relationship to the hypertensive vascular problem has not always been clear Obstruction with infection in the urinary tract, however, was seriously detrimental to the welfare of the hypertensive and arteriosclerotic cardiac patient Diabetes mellitus was another common complication Biliary tract disease was also frequently found

ARTERIOSCLEROTIC HEART DISEASE

Cases were classified under arteriosclerotic heart disease when there was evidence of generalized arteriosclerosis, coronary arteriosclerosis, aortic sclerosis (non-syphilitic), pulmonary arteriosclerosis, or fibrosis of the myocardium as defined by the Criteria for Classification and Diagnosis

Two hundred and forty-one patients or 24.1 per cent of the total, were listed under this heading The secondary etiologic factors are presented diagrammatically in chart 4 Hypertensive vascular disease was found to be the most common complicating factor, occurring in eighty-nine cases, or 36.9 per cent of the 241 cases

There were twenty-two patients with thyrotoxicosis and coronary sclerosis They were all over 40 years of age Syphilis was represented by only seventeen cases There were only ten cases of rheumatic infection in this combination These were patients in whom the rheumatic infection had apparently entirely healed and had been quiescent for years The frequent association of other diseases as mentioned in the hypertensive group also applied to the arteriosclerotic patients

THYROID HEART DISEASE

Heart disease of thyroid etiology as listed by the Criteria is as follows

Criteria for Diagnosis of Thyroid Heart Disease due to Adenoma with Hyperthyroidism or Exophthalmic Goiter

- 1 Evidence of hyperthyroidism and enlargement of the heart
- 2 Evidence of hyperthyroidism associated with abnormal cardiac function such as paroxysmal or permanent auricular fibrillation

Chart 5—Thyroid group

Criteria of Heart Disease Due to Myxedema

- 1 Evidence of hypothyroidism with enlargement of the heart, with or without cardiac insufficiency
- 2 Favorable response to the administration of thyroid extract

One hundred cases, or 10 per cent of the series, were classified in this group, of which ninety-three were

TABLE 1—Incidence in Hyperthyroid and Main Group

	Hyperthyroid Group (93 Cases)	Main Group (1 000 Cases)
Rheumatic.	30.1%	29.2%
Hypertension	26.8%	23.2%
Arteriosclerosis	23.8%	24.1%
Neurologic.	7.5%	8.0%
Syphilis	3.2%	9.7%
Pulmonary	5.3%	5.8%
Bacterial	1.0%	1.6%

hyperthyroid and seven were hypothyroid. In the hypothyroid cases, six were uncomplicated by any other known etiologic factor and one was complicated by hypertension and urologic disease. The group of thyrotoxic patients was the most interesting of the series, in that sixty-two cases (66.6 per cent) were complicated by organic or structural heart disease and, in addition to this, seven cases were complicated by neurocirculatory asthenia as presented diagrammatically in chart 5.

The common complicating factors in this group were rheumatic disease, hypertension and arteriosclerosis. The other etiologic factors, except congenital, toxic and trauma, were also encountered. Comparison of the incidence of these secondary factors with the incidence of the same factors in the main group show them to be similar (table 1).

The effect of thyrotoxicosis on the welfare of the structurally damaged heart was of great importance as to operative risk, prognosis and postoperative morbidity. The thyrotoxicosis exaggerated the primary cardiac problem, and thyroidectomy relieved this burden. In

those cases in which there were no other etiologic factors than thyrotoxicosis, in which thyroidectomy was performed, the cardiac situation was no longer a clinical issue, except in a few cases of recurrence of thyrotoxicosis.

In the Criteria for Classification and Diagnosis, "evidence of hyperthyroidism, associated with abnormal cardiac function such as paroxysmal or permanent auricular fibrillation" is listed as a basis for the diagnosis of hyperthyroidism. In our studies, auricular fibrillation, either paroxysmal or permanent, has been found only in the presence of other obvious factors and structural lesions, commonly rheumatic valvular disease, hypertensive vascular disease, coronary arteriosclerosis and myocardial fibrosis. It has been our impression that the primary basis for the occurrence of auricular fibrillation was the structural lesion and the thyroid toxemia the secondary exciting factor. In this small series the arrhythmia was not encountered in uncomplicated thyrotoxicosis. We are making a further search to clarify this issue in a larger series of thyrotoxic patients, and also to study frequency of structural pathologic changes.

Comparison of our statistics and other reports shows great variation. Flaxman's report from the Cook County Hospital lists an incidence of 2.6 per cent. In the New England area reported by Cabot and White and his associates the incidence is from zero to 2.9 per cent. In the West and Northwest, Coffin and Viko report incidences of 6.1 per cent and 9.3 per cent respectively. The high incidence of goiter in the Great Lakes area and northwestern United States is commonly accepted.

SYPHILITIC GROUP

The Criteria for Classification and Diagnosis of Syphilitic Heart Disease are as follows:

- 1 History of syphilitic infection and evidence of a characteristic structural lesion of the heart or aorta

Chart 6—Demonstration of the combination of syphilitic heart disease and other etiologic factors

- 2 A characteristic structural lesion of the heart or aorta without a history of syphilis but with a positive Wassermann reaction.

- 3 A characteristic structural lesion of the heart or aorta together with evidences of syphilitic disease, elsewhere, such as cerebrospinal syphilis, even in the absence of a positive Wassermann reaction or a history of syphilitic infection.

17 Cabot, R. C. The Four Common Types of Heart Disease J A M A 63 1461 (Oct 24) 1914
18 White and Myers, White and Jones, White P D Heart Disease New York, Macmillan Company 1932

We have followed these criteria with two exceptions. We have encountered two cases of syphilitic pulmonary arteritis with a cor pulmonale, one of which was proved at autopsy. There was no autopsy in the second case, but it was equally definite clinically.

Ninety-seven cases were classified under this heading and twenty-eight cases, or 28.8 per cent, were complicated by secondary factors, as demonstrated in

Chart 7—Neurologic group

chart 6. Only four cases of hypertension were encountered in this group, while in a similar study of indigent patients the combination of syphilis and hypertension was much more common.

Other authors report incidences of syphilitic heart disease as from 1.1 per cent to 21.4 per cent. That syphilis has been overlooked in some cases is probably true. The number of patients in this group was too small to calculate reliable figures as to age, sex and other factors.

NEUROLOGIC

The Criteria for Classification and Diagnosis gives the following:

Criteria for Diagnosis of Cardiac Psychoneurosis

1. Presence of definite psychoneurosis in the history or examination of the patient.

2. Presence of the symptoms and signs mentioned without structural cardiac disease being present or without its being present in sufficient degree to account for the symptoms.

Reflex Action. Certain patients may be subject to physiological disturbances of the heart action as a result of reflexes arising in other parts of the body and especially in the abdominal viscera. Premature contractions, paroxysmal tachycardia and sinus arrhythmia are the most frequent disturbances of such origin.

We have considered the psychoneurotic group and the reflex group together in this study. Eighty patients were classified in this category. In fifteen cases, or 18.7 per cent, an organic lesion complicated the syndrome of neurocirculatory asthenia. These complicating factors are presented in chart 7.

Thyrotoxicosis was listed in seven cases. Six of these patients came under our observation after thyroidectomy. An effort was made to determine whether the thyrotoxicosis had been an error of diagnosis or whether the two entities may occur in the same individual. These patients had been examined by numerous physicians and consultants with varied opinions. It was impossible to render a decision. We had the opportunity of studying our patient before and after thyroid-

ectomy. We failed to discern the functional syndrome of neurocirculatory asthenia prior to operation.

In this group there were five cases of rheumatic heart disease, two of hypertension and one of pulmonary and arteriosclerotic disease.

PULMONARY HEART DISEASE

Criteria for Diagnosis of Heart Disease due to Pulmonary Emphysema

1. The presence of pulmonary emphysema.
2. Evidences of cardiac insufficiency with more than usual cyanosis.
3. Evidences of enlargement of the right ventricle.

Only fifty-eight cases, or 5.8 per cent, were classified in this group, of them forty-one cases (70.6 per cent) were associated with other etiologic factors, as presented in chart 8, showing their frequency. We are inclined to believe that we have overlooked the pulmonary factor more often than any other.

TABLE 2.—Types of Pulmonary Disorders in this Series

Condition	Cases
Bronchiectasis	25
Asthma and bronchitis	18
Tuberculosis	8
Syphilis	6
Hodgkin's disease	2
Deformity of the spine and thorax	2
Unknown	2
Metastatic cancer of lung	1
Actinomycosis	1

The following types of pulmonary pathologic conditions were encountered in this series as shown in table 2.

In one case of hay fever congestive heart failure developed in the second trimester of pregnancy. One patient in this group died with coronary thrombosis, and autopsy revealed a cor pulmonale. The only cause demonstrated for the emphysema and the increased size

Chart 8—Demonstration of the combination of pulmonary heart disease and other etiologic factors

of the right ventricle was a history of continuous athletic training over a period of twenty-two years. A well marked pulmonary arteriosclerosis was also found.

Evidence of enlargement of the right ventricle was seldom of value in establishing this diagnosis unless the patient was under observation for more than a year, with two roentgenograms for comparison. Right axis deviation in the electrocardiogram was observed as a development in the later stage of the disease.

BACTERIAL GROUP

The criteria for the diagnosis of Bacterial Endocarditis are listed as follows

Evidence of cardiac valvular disease or of a congenital abnormality associated with

- 1 Signs of sepsis
- 2 Positive blood culture.
- 3 Embolic phenomena

Sixteen cases, or 16 per cent, were classified in this group, all due to *Streptococcus viridans*

All of these were complicated by either rheumatic (fourteen cases) or congenital disease (two cases)

One case was of unusual interest because of the combination of subacute bacterial endocarditis and a severe thyrotoxicosis

CONGENITAL GROUP

Congenital entities listed in the Criteria include Anomalies of position of the heart or great vessels, coarctation of the aorta, patent ductus arteriosus, pulmonic stenosis, patency of the septum and congenital defect of the pericardium

Only six cases were encountered five of which were complicated by other etiologic factors. In four cases a superimposed rheumatic valvulitis developed, in two cases subacute bacterial endocarditis, in two toxic factors and in one case a deformity of the thorax

TOXIC GROUP

The Criteria as listed for the toxic group are as follows

Evidence of a definite toxin (bacterial, mineral, vegetable) associated with

- 1 Structural lesion of the heart
- 2 Abnormal cardiac function

Twelve cases, or 12 per cent, were included in this group. Seven of the cases were due to diphtheritic infection and five were secondary to pneumonia. Secondary etiologic factors were present in eight cases, rheumatic infection, six cases, congenital disease, two cases, arteriosclerosis, one case, and hypertension, one case

TRAUMATIC GROUP

"Trauma. Structural cardiac lesions occur as the result of penetrating wounds, severe blow upon the chest or crushing injuries." This again is quoted from the Criteria

One case of this type is included in the series of a traumatic pericarditis as a result of a severe crushing injury of the thorax

COMMENT

While a study of this type is of value in determining the relative frequency of the various types of cardiac disease in a given geographic area and allows comparison with other areas, we were impressed that it fails to convey a correct impression of many of the practical issues in the course of a cardiac case

A majority of the minor factors are neglected in presentation of these data. Respiratory infections, dietary factors, pregnancy, emotional crises, overexertion, surgical procedures, anesthesia effects, and many other factors cannot be included or correctly evaluated

The combination of two or more etiologic factors in one patient presents an interesting field of study. In this series 31.6 per cent, or 316 cases of the 1,000, were in this group, with multiple etiologic factors. Again

it is necessary to point out the inadequacy of statistical studies to portray accurately such relationships. To have an exact analysis of this problem one should include cases that are under observation over the entire clinical course of the heart problem

In the rheumatic heart group, for example, only 22.2 per cent are complicated by secondary etiologic factors. If this entire group had been studied over the complete rheumatic heart cycle, undoubtedly a greater number would be found to have been complicated by hypertension, arteriosclerosis, goiter or syphilis. Only fourteen cases were complicated with subacute bacterial endocarditis, or 4.7 per cent. White¹⁸ quotes an incidence of 4 per cent. Karsner and Bayless¹⁹ in their studies of coronary arteries in rheumatic disease report that "rheumatic fever regularly produces disease of the coronary arteries." Only ten cases, or 2.9 per cent, in our series were classified in the arteriosclerotic group

Lisa and Chandlee²⁰ reported a study of six cases of the combination of syphilis and rheumatic infection. In one case the role of syphilis equaled that of the rheumatic infection, while in five cases the rheumatic infection preponderated. In this series we never encountered this combination. In our studies in the Cook County Hospital, however, it is of frequent occurrence clinically, and usually in Negro patients, as the foregoing observers indicate. However, we have never been able to prove conclusively the identity of the two lesions anatomically

The combination of syphilis and hypertension occurred in only three patients, and syphilis and arteriosclerosis occurred in fifteen cases. Horine and Weiss²¹ studied the relationship of syphilis and hypertension and reported that "syphilis had no etiologic bearing on essential hypertension." This again is a combination frequent in the Negro race and in the indigent patient and much less common in private cases

In completing this survey, we have been impressed with the value of classifying our patients into etiologic groups. Our attention has been better directed toward treatment of the causative factors with better therapeutic results. Prognosis has been simplified

While many cases of cardiac disease may be readily classified in the major groups of rheumatic, hypertensive or arteriosclerotic heart disease, there are no doubt frequent errors. The factor of error is reduced in those patients under observation for long periods of time. The history taken from the patient has been a factor of prime importance, as well as the physical examination. One cannot underestimate the necessity of the fluoroscopic, roentgen and electrocardiographic studies

Lastly, one cannot fail to learn that each cardiac patient presents a highly individual problem, with one or more essential causative factors and many minor issues affecting his clinical course

Clinical Notes, Suggestions and New Instruments

ACUTE EXACERBATION OF LATENT GONORRHEAL URETHRITIS AFTER FIFTY YEARS' FOL- LOWING PROSTATECTOMY

CLARENCE K. FRASER, PH B AND W J PAUL DYE M D
WOLFFBORO N H

It is deemed of interest to report this case, since careful search of the literature reveals no similar ones. Many authors, in general discussion, mention that gonococcal infection may recur following operations but mention no specific instances. Dr A. L. Wolbarst¹ says 'It is a curious but explainable fact that a long-forgotten gonococcal infection may be revived and an acute inflammation develop as the result of an injury, inflammation, or a surgical operation in some distant part of the body'. Similar general statements are the only type that are found in the literature.

REPORT OF CASE

History—T. D. H., a white man, aged 70, retired from business, admitted to the Huggins Hospital, Oct. 12, 1934, complained chiefly of complete inability to void for the preceding twelve hours. For the past year, gradually increasing in severity to date, he had noticed dysuria, nocturia, frequency and feebleness of the stream of urine along with diminished, unrelieving amounts being passed at a single micturition.

The past history was essentially irrelevant except for a definite acute attack of gonorrheal urethritis followed by a course of metal urethral sounds fifty years previously. This attack was apparently successfully treated, and there had been no urethral discharge or other genito-urinary symptoms since that time. The patient later became married and there are now two grown mature children as a result of this union. The wife and children are and have been quite healthy in every respect.

Examination—Physical examination revealed but few senile changes consistent with a relatively rugged man of his age whose only complaint was inability to void.

Rectal examination showed a diffuse and symmetrical enlargement of the prostate the palpated surface being smooth and firm. Grams stains of prostatic smears revealed from two to five leukocytes per high power field but no organisms.

There was no urethral discharge nor could any be expressed by manual manipulation. The easy passage of a number 18 French soft rubber catheter through the urethra to the bladder evidenced the absence of any urethral strictures.

Laboratory examination on admission revealed red blood cells, 3,580,000, hemoglobin 60 per cent, white blood cells 13,900 with 80 per cent polymorphonuclear leukocytes. Several Kahn tests of the blood were negative. Blood nonprotein nitrogen was 60 mg per hundred cubic centimeters, subsequently 43 mg prior to the second stage of the operation. Urine showed a trace of albumin, many pus cells and a few red blood cells, all of which cleared under suprapubic drainage.

A first stage suprapubic cystostomy was done October 26 and on November 14 the second stage of the suprapubic prostatectomy was carried out. A pathologic report gave a diagnosis of benign diffuse hypertrophy of the prostate.

Clinical Course—The patient had a generally normal post-operative course abetted by a whole blood transfusion at the end of the second week. A creamy purulent penile discharge was noted for the first time, December 3, about three weeks after the second stage prostatectomy. Many smears were made of this urethral pus by different, competent individuals on separate days such smears being stained by Gram's method and examined microscopically. An abundance of Gram-negative intracellular diplococci typical of gonococci were found on each occasion. This discharge persisted until about three weeks

after voluntary micturition through the urethra had been established, thereafter no pus could ever be seen or expressed from the meatus.

Subsequent urologic examination showed the presence of several areas of stricture in the posterior urethra, presumably due to the gonorrheal urethritis, which required the use of sounds for dilation. The passage of sounds, however, did not stir up any further urethral discharge or symptomatic burning, and the urine has been free from albumin and pus since three weeks after the healing of the suprapubic wound and the disappearance of the urethral pus.

SUMMARY

There are no reports in the literature of exacerbation of latent gonorrheal urethritis following prostatectomy.

This patient had a definite gonorrheal urethritis at the age of 20 years. This was successfully treated without sequelae. The patient married and became the father of two normal, healthy children, and his wife never had any symptoms or signs of gonorrhea. The patient himself had no signs of urethritis from the time of the first, apparently successfully treated attack until a suprapubic prostatectomy was done fifty years later.

Prostatectomy apparently caused an acute exacerbation of the gonorrheal urethritis. Three weeks afterward typical gonorrheal pus with gonococci seen on repeated Gram's stains of the smears taken of the pus were noted. This discharge persisted for about three weeks after urine was passed through the urethra for the first time since operation and has not been seen since. Subsequent strictures of the posterior urethra, presumably due to this last attack of gonorrheal urethritis, necessitated the use of metal sounds for dilation.

SPONTANEOUS RUPTURE OF COLD ABSCESS OF CHEST WALL REPORT OF A CASE

ALLEN S. JOHNSON, SPRINGFIELD, MASS.

The following case of spontaneous rupture of a cold abscess of the chest wall with drainage of a pleural effusion is reported because of the apparent rarity of the phenomenon. Meade¹ says in regard to a tuberculous abscess of the soft parts of the chest wall that "whether it starts in the pleura or other deep seated layer the process always advances outward either directly or after a lateral deviation. Practically all writers agree that inward spread is unknown". In the case herewith reported, however, this abscess developed spontaneously, not in a needle tract after aspiration, and ruptured both inward and outward, thereby replacing the pleural effusion with a pneumothorax. The studies of Leggett² and Emerson³ indicate that such a sequence of events is most unusual in the case of a pleural effusion not secondarily infected and I can find no report of such a phenomenon in an extensive search through the literature on this subject.

G. M., a man, aged 49, a clerk, seen by another physician five weeks before admission to the hospital complained of cough and dyspnea. The patient's father had had tuberculosis and two uncles had died of the disease. The patient himself had always been susceptible to respiratory infections which were often accompanied by dry pleurisy. He frequently had a temperature and often had drenching night sweats. He had had a productive cough attributed to smoking since early adult life and had had mild hemoptyses on several occasions. It was difficult to date the onset of the present illness, but the dyspnea had been growing progressively worse for several weeks. The significant physical signs at this time were those of a right-sided pleural effusion. Roentgenograms showed the right lung to be almost entirely collapsed by fluid extending up to the third interspace anteriorly; above this was air which further collapsed the lung. This suggested that the effusion had

occurred as a sequel to a spontaneous pneumothorax but a careful history yielded no evidence of such a sequence of events. The left upper lobe showed extensive tuberculous infiltration, and there was some mediastinal shift to the left.

The patient was then admitted to the local tuberculosis hospital. The sputum was loaded with tubercle bacilli on all occasions. Blood counts were not remarkable. Blood Hinton and Wassermann tests were negative. The sedimentation rate (Cooper's method) was a fast normal (70 per cent in one hour). A diagnostic chest tap posteriorly ten days after admission revealed slightly cloudy straw colored fluid. A smear showed no organisms or pus cells and culture yielded no growth.

The patient's course during the next two months was not remarkable. He ran an irregular temperature up to 100.6 °F, a pulse of 100 and respirations of 25. A reddish, brawny, itching area of induration about 6 cm in diameter then developed in the seventh interspace in the right nipple line. During the next few days this became definitely painful and fluctuant. In order to rule out rib involvement by x-ray, 3,000 cc of pleural fluid was aspirated posteriorly. Even this large amount failed to lower the fluid level below the abscess, but the danger of an abrupt shift of the mediastinum contraindicated further aspiration at this time. The fluid removed was cloudy and straw colored with a specific gravity of 1.020 and showed numerous white blood cells. No tubercle bacilli or other organisms were found in smears, and culture on ordinary mediums yielded no growth. The patient was having very little systemic reaction from the abscess and only slight local pain so that evacuation of the abscess was not imperative. While we were waiting for the return of our x-ray technician, however, the abscess ruptured spontaneously about three weeks after it was first noticed. Such pus as may have been evacuated was obscured by the enormous quantity of yellow watery fluid, which poured through the sinus from the pleural cavity, so that cultures were not obtainable before contamination had occurred. Apparently what had appeared to be a superficial abscess gradually working its way toward the surface had ruptured inward and outward at the same time. Roentgenograms now showed the pleural effusion to have been completely drained and replaced by a pneumothorax, which was maintaining the lung and mediastinum in the same relative positions. The ribs did not appear to be involved. During the development of this abscess and after its rupture the patient's temperature, pulse and respirations remained about the same, but he volunteered the information that he now felt much better and had a better appetite than he had had for months.

A few days after the rupture of the abscess, daily irrigations of the sinus tract were instituted with azochloramide, 1:3,300. These were well tolerated by the patient and cultures from the sinus and by aspiration through pipets introduced into the pleural cavity showed no growth a month after rupture of the abscess. The overgrowth of granulation tissue in the sinus then began to interfere with adequate irrigation of the cavity and secondary infection developed. The clear serous discharge became purulent and the patient began to lose the weight which he had gained during the preceding two months. A month of daily irrigation with gentian violet was of no evident benefit, and the azochloramid irrigations were resumed. Six weeks of this treatment have materially lessened the amount of the discharge, though it is still purulent. The patient feels much better, however, and his renewed appetite has resulted in his regaining all the weight that had been lost. The roentgenogram is almost identical with that taken after the rupture of the abscess four and one-half months ago. He is still afebrile and is allowed bathroom privileges. The only change in the sinus is the loss of 4 square centimeters of integument about the opening with the production of a shallow, indolent ulcer, which has gradually increased in size in spite of ultraviolet irradiation and various local applications.⁴

121 Chestnut Street.

4. A supply of azochloramid for the treatment in this case was furnished by Dr. Elliott Weyer of Wallace and Tiernan, the manufacturers, Belleville, N. J.

Special Article

GLANDULAR PHYSIOLOGY AND THERAPY

THE INTERNAL SECRETION OF THE PANCREAS

C. H. BEST, M.D., D.Sc. (Lond.), F.R.C.P. (Can)
TORONTO, ONT.

NOTE.—This article and the articles in the previous issues of THE JOURNAL are part of a series published under the auspices of the Council on Pharmacy and Chemistry. Other articles will appear in succeeding issues. When completed the series will be published in book form.—Ed.

The time-honored and productive physiologic methods of studying the function of an organ are (1) to remove it completely or in part and to observe the abnormal effects attributable to its absence, and (2) to make extracts of the tissue in various ways and to study the mechanism of action of the fractions that are found to possess specific physiologic potency. The pancreas has lent itself admirably to this procedure in the case of both internal and external secretions. Since this article is, in large part, a preface to a consideration of the therapeutics of pancreatic preparations, the space available will be devoted to a consideration of the internal secretion.

REMOVAL OF THE PANCREAS

When the pancreas is completely removed from a dog (and the effects in the other mammals that have been studied are similar), a characteristic syndrome rapidly develops.¹ When a diet including all the known essentials is provided, the animals may live indefinitely if adequate amounts of insulin are administered. The diets used have included preparations containing the pancreatic enzymes and a source of choline (or of related substances with similar effects), which apparently is necessary to prevent deposition of excessive amounts of fat in the livers of these animals. The dogs recover rapidly from the depancreatization and appear normal, but the diabetic state quickly supervenes when insulin is discontinued. The sugar content of the blood begins to rise within a very short time, the length of which depends on the size of the last dose of insulin, and increases from the normal level of from 0.08-0.11 per cent to 0.20-0.40 per cent or higher within twenty-four hours. The urine gives a positive Benedict qualitative test for sugar when the blood sugar rises above approximately 0.16 per cent. This point, the so-called renal threshold, is the level of blood sugar above which large amounts of sugar are excreted in the urine. In some animals the "threshold" rises when the diabetic state is allowed to persist (There are minute amounts of dextrose and some other sugars in normal urine.) The excretion of nitrogen is increased, and this may be taken to indicate protein breakdown, but some doubt exists as to the accuracy of the conventional calculation, i. e., protein-urinary nitrogen $\times 6.25$, particularly when this is applied in short-term experiments. The amount of dextrose formed from protein in the diabetic subject has been calculated from the increased dextrose output when protein is given to the phlorhizinized dog

From the Department of Physiology and the School of Hygiene University of Toronto.

¹ von Mering, Joseph and Minkowski, O. Diabetes mellitus nach Pankreasextirpation. Arch. f. exper. Path. u. Pharmacol. 26: 371 (Jan.) 1889.

It is very doubtful whether phlorhizin poisoning and pancreatic diabetes are comparable conditions, but studies of the former suggest that the amino acids glycine, alanine, cystine, aspartic and glutamic acid yield dextrose but that others, such as tyrosine, leucine and phenylalanine, do not yield dextrose but increase the excretion of ketone bodies. The ratio of dextrose to nitrogen excreted in phlorhizin poisoning is 3.6:1, but this ratio is rarely observed in depancreatized dogs and indeed that obtained is so variable that in most circumstances little significance can be attached to it. The ratio is low under certain conditions in animals on a high protein diet, and there is evidence that the addition of small amounts of fat may increase it somewhat. The question of sugar formation from fatty acids will be briefly discussed later. It is established that glycerol may be converted to sugar, so some extra sugar excretion may be expected when glycerides, i. e., neutral fats, are administered. (Glycerides are reported not to increase the sugar excretion of a phlorhizinized animal.) In the fasting diabetic subject the blood sugar and sugar excretion are maintained at high levels. The sugar is apparently formed from body protein largely in the liver, since the blood sugar of the diabetic subject falls rapidly after hepatectomy. The loss of protein contributes to the rapid decrease in body weight observed in depancreatized animals.

The disturbed metabolism of fat in the depancreatized animal is indicated by the accumulation of the ketone bodies in the blood and by the excretion of excessive amounts in the urine. The ketosis in a fat dog is greater than in a lean one, but this species is characterized by its efficiency in metabolizing fats without ketosis. The loss of body fat is rapid, but the ketosis may be so severe even in this species that the animal dies of coma before the fat reserves are depleted.

Beta-oxybutyric acid is a relatively nontoxic product. It can be estimated by oxidizing to acetone and determining the amount of the latter substance. Aceto-acetic acid, on the other hand, is more toxic probably because of its enolic form $\text{CH}_2\text{COH}-\text{CHCOOH}$. It is stated that this substance stimulates the respiratory center and depresses the higher centers of the brain, causing in these ways "air hunger" and the dimmed perception and loss of consciousness of diabetic coma. The evidence does not justify the conclusion that aceto-acetic acid is the sole cause of this syndrome. Aceto-acetic acid is decomposed in the bladder and lungs, and acetone and carbon dioxide are formed. Acetone, $\text{CH}_3-\text{C}(=\text{O})-\text{CH}_3$, is excreted in the urine and expired air. Aceto-acetic acid in blood may be converted by mild hydrolysis to acetone and the latter can be estimated by various procedures.

The neutral fat content of the blood increases, owing probably to the augmented rate of mobilization of depot fat, and there is also a rise in cholesterol esters and phospholipids. Since there are small amounts of the ketone bodies present in normal blood, it is preferable to consider these substances as intermediary products in the oxidation of fatty acids. When the rate of breakdown of the acids is excessive, as in pancreatic diabetes, these ketone bodies accumulate in the blood.

A little space may be given here to the two closely related questions (1) the formation of sugar from fatty acids in the depancreatized animal, and (2) whether pancreatic diabetes is characterized by an overproduction of sugar, an underutilization of sugar or both. With regard to the first, it is well established that this transformation takes place in plants, and there

is considerable indirect evidence that may be interpreted as favoring this possibility in animals, but direct proof of the change is conspicuous by its absence. It is difficult to prove that the change cannot take place, and failures to obtain evidence in favor of it may be due to the method of investigation. In spite of the attention this question has attracted, it must be left in this unsatisfactory state. A final answer would do much to clarify the field.

If overproduction of dextrose were the only abnormality in diabetes, fat as well as protein would be required to furnish material. Very few authorities will deny that the evidence for the increased rate of production of sugar from protein in pancreatic diabetes is satisfactory. While there is, in my opinion, an abundance of evidence that the depancreatized dog can still burn sugar—all the criteria of sugar combustion in the normal have been satisfied—it is not permissible to conclude that there is no interference with this process. Convincing experimental evidence for deficient utilization of dextrose in diabetic heart muscle was at one time thought to be available, but it now appears that the chief fuel of heart muscle is lactic acid which is taken up from the blood, and not dextrose. The amount of sugar utilized by a hepatectomized dog is apparently definitely less when the pancreas also is removed. The rapid sugar utilization in the hepatectomized diabetic animal and the production of a diabetic condition by the administration of the diabetogenic substance of the anterior pituitary, which apparently acts by stimulating the liver to produce more dextrose, tend to emphasize overproduction rather than underutilization. It is preferable to consider, however, that both mechanisms play a part in the production of the diabetic condition and to concentrate attention on the development of quantitative methods by which accurately to determine the extent of the overproduction or underutilization.

Studies of isolated muscles appeared to indicate that carbohydrate alone is burned, but there are now many facts which suggest that other food materials are used. While the possibility exists that these may be converted to sugar in the muscle before use, it is much simpler and more in accord with the evidence to consider that fat and protein as well as sugar may be used directly.

The respiratory quotient of the depancreatized animal assumes the characteristic low level of from 0.69 to 0.73 and is not raised when sugar is given. Under certain conditions in animals that have previously received a high protein diet and insulin, the quotient may be somewhat higher. The low quotient may indicate combustion of fat, but if any process, such as conversion of fat to sugar, which gives a very low quotient, should be taking place the quotient might indicate the resultant between sugar combustion, fat combustion and the conversion. When the pituitary gland is removed from the depancreatized dog, the quotient is raised. When the liver is removed from a depancreatized dog, the quotient also rises, indicating either that relatively more sugar is being burned or that conversions giving a low quotient are taking place to a smaller extent. Since more than one interpretation of a quotient is possible, great caution must be observed in drawing conclusions with regard to its significance. This ratio is often used, because of its convenience, to describe the results of physiologic research, but the investigator who makes use of this "instrument of attack" should not be accused of believing in its unitarian significance unless he specifically states his position.

While the glycogen content of the muscles of a depancreatized animal may be reduced below the normal level, appreciable amounts remain during the life of the animal. There is no diminution of heart muscle glycogen, and recently convincing evidence for an increase has been obtained. Liver glycogen falls to very low levels. A very slight increase in both muscle and liver glycogen can be produced by giving large amounts of sugar without insulin.

The excretion of phosphate is increased in the depancreatized animal. The administration of sugar or epinephrine does not cause the prompt fall in the inorganic phosphate of the blood observed in normal animals. These results suggest that sugar may produce its effect through liberation of insulin, but in the light of the effect of raising the blood sugar on the rate of sugar production by the liver in depancreatized dogs receiving a constant amount of insulin the latter organ as well as the pancreas comes under suspicion.

The diabetic animal is very susceptible to infections, but it is not established that this is due to the raised sugar content of the tissues. The specific antibodies are not significantly altered in amount, but other defense mechanisms may be made less effective by the abnormal metabolic condition that exists. Pathologic conditions are observed with considerable frequency in the eyes of diabetic animals. The liver may undergo extensive fatty degeneration and there may be an accumulation of very large amounts of neutral fat. Dietary factors play a large part in determining the extent of this change.

While there is considerable variation in the length of life of the depancreatized dog or cat, most individuals fed on a mixed diet do not live for more than two weeks without insulin. It is now established, however, that when the anterior pituitary is also removed the animal (dog) may live for at least a year and exhibit at most only a mild form of diabetes. Severe diabetes is produced under these conditions by administration of the diabetogenic substance of the anterior pituitary, but the maximum duration of this form of diabetes is not yet established. The condition is alleviated by insulin. Since the hypophysectomized pancreatectomized dog has apparently retained considerable ability to metabolize sugar (dextrose tolerance tests may give normal results), and the liver and muscle glycogen are within normal limits, it must be admitted by all that the pancreas is not essential to sugar combustion or glycogen formation under certain conditions at least.

These facts suggest to the physiologist the following classification of the diabetic state:

- 1 Increased glyconeogenesis due to lack of insulin, i. e. hypo-insulinism
- 2 Increased glyconeogenesis due to excess of the diabetogenic substance of the anterior pituitary or in part perhaps to hyperactivity of the adrenal² or thyroid glands
- 3 Increased glyconeogenesis not attributable to endocrine disturbances. While several factors, i. e. nerve impulses, products of infection, or changes in acid-base equilibrium, may affect the liver cells directly, endocrine disturbances may perhaps be an inevitable concomitant or result of these abnormal conditions. For this reason it is by no means certain that a diabetic state due solely to liver disturbances will be encountered. A type of hypoglycemia, however, attributable to extensive dam-

age of liver cells, is recognized, and there are already certain bits of experimental evidence suggesting that the reverse, i. e. an overactivity, may be produced—possibly in some cases as the first stage of injury but conceivably, in other instances, by more physiologic mechanisms.

While it is possible to produce 1 and 2 experimentally as separate entities for a time, at least, it is probable that overlapping of the factors causing overproduction may occur clinically. In each of these three types there may be an under-utilization of dextrose by the tissues. This under-utilization may be, as many contend, the primary disturbance, but, on the other hand, it may be secondarily produced by the products of abnormal metabolic conditions of the liver. The favorable effect of insulin throws very little light on the factor or factors responsible for the overproduction or under utilization.

EFFECTS OF THE ANTIDIABETIC HORMONE

It is well established that insulin restores to the depancreatized animal its ability to metabolize sugars and fats in a normal manner. The excessive breakdown of protein is prevented. The ketosis rapidly disappears. Glycogen accumulates in large amounts in the liver. Muscle glycogen may be increased. The respiratory quotient rises when sugar is made available, or in fact when insulin alone is administered. Animals recover their ability to deal with infective agents. In brief a well treated depancreatized animal is difficult to distinguish from a normal one. There is always the difficulty, of course, that in the animal without a pancreas relatively large amounts of insulin are made available two or three times a day, while in the intact animal small or large amounts are presumably liberated from the pancreas as the need arises or conceivably at an approximately constant rate. Adult depancreatized dogs on an adequate diet³ including the enzymes of the external secretion of pancreas have been maintained in good condition for more than four years. It cannot be stated, however, that these animals enjoyed at all times the fullest health, and there is ample opportunity to effect improvements in the details of treatment.

SOURCE OF INSULIN

While it is reasonable to suppose that small amounts of insulin are present in tissues other than the pancreas, methods are not yet available for their detection. Blood provides an exception to this generalization, but the active substance is detected by the intravenous administration of the whole blood and not by extraction of the insulin from the tissue. At least six groups of investigators, including the early workers on insulin in Toronto, were led for a time by errors in testing and by artefacts to believe in the wide distribution of appreciable amounts of insulin. In the mammalian organism the pancreas appears to be the only organ that manufactures or stores insulin.

The alpha and beta cells of the islands of Langerhans have been extensively studied and a third type, the gamma cell, has been detected. The beta cells, which occupy the periphery of the islets and whose granules are soluble in alcohol, are thought to be the source of insulin.

The main points of evidence which indicate that insulin is produced in the islet cells are as follows: 1. The active substance is found in degenerated pancreas

² The alleged relationship of the adrenal to carbohydrate metabolism is discussed more in detail in the papers by Rogoff (*The Adrenal Medulla*, J. A. M. A. 104:2091 [June 8] 1935) and by Loeb (*The Adrenal Cortex*, J. A. M. A. 104:2177 [June 15] 1935) in this series.—Ed.

³ Evidence is accumulating that certain accessory food factors may exert an appreciable effect on the intensity of glycosuria in pancreatic diabetes.

in which the loss of acinous tissue has proceeded much more rapidly than that of the islet cells.⁴ Ligation of the pancreatic ducts eventually produces a decrease in the insulin content of the pancreas, but, when very few enzyme-producing cells remain, moderate amounts of insulin may still be extracted.² There are relatively large amounts of insulin in the principal islet of teleostean fishes, in which few enzyme-producing cells are found.⁵ 3 Histologically, the islets are glandular structures the obvious outlet for the secretion of which is through the blood stream.⁴ When large amounts of carbohydrates are given to partially depancreatized dogs, characteristic lesions (hydropic degeneration) are found in the beta cells, which disappear when the carbohydrate is eliminated from the diet or is balanced by insulin.⁵ 5 In the clinical condition known as hyperinsulinism, the pancreas liberates abnormally large amounts of insulin. In many of these cases there are definite tumors of the islet cells. After the operative removal of these masses of islet cells the blood sugar is maintained at higher levels.

LIBERATION OF INSULIN

The arrangement of the capillary loops about the islet cells and the reported scarcity of lymph channels provide morphologic evidence in favor of the capillary blood stream as the pathway by which insulin reaches the systemic circulation. It is important to remember that insulin passes first to the liver.

While there are many pieces of experimental evidence which support the conclusion that the level of blood sugar is an important factor in the regulation of insulin liberation, the possibility that a decrease in the rate of discharge of sugar from the liver may also be produced when the blood sugar is raised is frequently overlooked. Increased deposition in or utilization by muscle is probably not an important factor in these very short experiments. When insulin liberation is maintained at a constant level in the depancreatized animal, the curve of blood sugar following an injection of dextrose may be very similar to that obtained in an intact animal. Removal of the liver produces the diabetic type of curve.⁶ However, the injection of small amounts of dextrose into the artery supplying a pancreas grafted into the neck of a depancreatized dog or into the pancreatic artery in a decerebrate cat causes a prompt lowering of blood sugar. In the latter case the effect was not obtained when the splenic or portal vein was used. If these results on decerebrate cats can be accepted, they provide evidence for the chemical control of insulin liberation through an action of the dextrose on structures within the pancreas, but the effect of a raised blood sugar on the rate of discharge of dextrose from the liver must also be considered. The results of experiments with denervated pancreatic grafts suggest that the pancreatic effect is exerted directly on the islet cells. These manifestations indicate that the nerve control is not essential. The nerve impulses that affect the islet cells are apparently conducted by the vagus. Vagus fibers have been traced to the islet cells, and nonmedullated branches are said to pierce them. The results of stimulating the vagus appeared to be clear cut and the pathway was traced by one group of investigators to the hypothalamic region, but other workers

have as yet been unable to confirm these observations. The effect of vagus impulses on the rate of sugar production by the liver requires further investigation, but the possibility that this mechanism is the one effective in lowering blood sugar must be considered.

THE MECHANISM OF ACTION

In the diabetic patient there is evidence that insulin enables more sugar to be burned, since the oxygen consumption is increased and the respiratory quotient rises. Some of the dextrose that disappears may be accounted for by the rise in liver glycogen, and there may be an increase in muscle glycogen. Increase of glycogen and rate of oxidation apparently account for all the sugar that disappears. The decreased nitrogen excretion indicates inhibition of glyconeogenesis.

In the normal animal the slight increase in oxidation and the deposition of glycogen in muscle apparently account for practically all the sugar that disappears. In adult animals of all the species that have been studied, liver glycogen does not increase.⁷ The increase in liver glycogen in young rabbits is a secondary effect, probably due to liberation of epinephrine. It has been argued that the deposition of muscle glycogen represents only an effect of abnormally large amounts of insulin, but small doses do not cause the disappearance of sufficient dextrose, in addition to that which is oxidized, to provide building material for the minimum glycogen increase, which can be accurately determined. Convincing direct evidence that large doses of insulin inhibit glyconeogenesis in the normal animal is not available, but this possibility is strongly supported by the results of several series of experiments.

INTERFERENCE WITH THE ACTION OF INSULIN

Other Hormones—There are five internal secretions the action of which may be considered to be antagonistic to that of insulin. There is no evidence of any chemical interaction of these hormones with the anti-diabetic substance. Epinephrine causes a prompt mobilization of liver glycogen and probably somewhat later the conversion of muscle glycogen to lactic acid, which is in turn converted to dextrose or glycogen or both in the liver. The suggested action of epinephrine in inhibiting oxidation of dextrose is not well supported by experimental evidence.²

Removal of the adrenal cortex leads in some species to hypoglycemia, which is alleviated by injection of extracts secured from cortical tissue. The mechanism of action of such extracts is not established.²

Thyroxine, by making liver glycogen more easily mobilized and also probably by accelerating glyconeogenesis, tends to produce hyperglycemia. On the other hand, the increased oxidation of dextrose in the tissues of a thyroxinized animal exerts the opposite effect on blood sugar. In the first stages of hyperthyroidism there is a hyperglycemia and a decreased effect of insulin. In the later stages there may be severe hypoglycemia without insulin and a great susceptibility to the antidiabetic substance.⁸

While posterior pituitary extract raises blood sugar and interferes with certain of the actions of insulin, it is not established whether the oxytocic or the pressor principle or both exert the effect. Furthermore, the evidence as to whether or not posterior pituitary extract acts through the adrenals is still controversial.

⁸ Burn J H and Marks H P. The Relation of the Thyroid Gland to the Action of Insulin. *J Physiol* 60:131 (July) 1925.

In certain species, at least, the diabetogenic substance of the anterior pituitary appears to be a very powerful antagonist of insulin.⁹ Hypophysectomized dogs, even after removal of the pancreas, may exhibit profound hypoglycemia. They are very susceptible to insulin. The information at present available indicates that the liver is essential to the action of the diabetogenic substance, which apparently acts, in large part at least, by stimulating glyconeogenesis.

Enzymes—Insulin is destroyed by pepsin-hydrochloric acid and by the activated proteolytic pancreatic enzyme. The pancreas may, however, be incubated aseptically at neutral or acid reaction without loss of the antidiabetic substance. Insulin is relatively unstable in alkaline solution. There is apparently an enzyme system in blood which is capable of activating insulin, but its characteristics have not been extensively studied.

Reaction of Tissues—Since insulin acts on the cells of the liver and muscles, factors that influence these tissues, acidosis for example, may modify insulin action. Furthermore, since the liver is so largely responsible for the regulation of blood sugar, influences affecting this organ may cause a change in sugar content quite apart from the action of insulin. A change in the acid-base equilibrium of the body toward the acid side renders injected insulin less effective.

Products of Infection—The toxic products elaborated by many micro-organisms may interfere with the action of insulin. There is experimental evidence (1) that the insulin content of pancreas is decreased in certain severe infections, but this does not necessarily indicate a decreased rate of liberation of the hormone, (2) that the adrenal and thyroid glands are stimulated to release more of their internal secretions, and (3) that the synthesis of glycogen from lactic acid in the liver is inhibited. Certain toxins may act on one or more of these mechanisms, but investigation of this field is still in the preliminary stages.

Anesthetics—All anesthetics interfere more or less with the action of insulin. More or less asphyxia is produced by all general anesthetics. In asphyxia acid products tend to accumulate. Chloralose and amytal cause less disturbance of carbohydrate metabolism than some other anesthetics.

HYPERINSULINISM

The tendency to refer to all clinical cases of spontaneous hypoglycemia, which may be due to (1) liver injury or to (2) deficiency of anterior pituitary secretion, adrenal insufficiency or other causes, as well as to (3) liberation of excessive amounts of the internal secretion of the pancreas, as hyperinsulinism should be combated. The signs of hypoglycemia in these various conditions may of course be identical, but hyperinsulinism is established only when removal of a tumor of islet cells corrects the condition. It is possible that general hyperplasia of islet tissue is responsible for some cases of hypoglycemia, but further study is needed to settle this point. When a large part of the pancreas is removed and the hypoglycemia is alleviated, which is the desired clinical result, the finding does not prove that the internal secretion had been liberated in abnormally large quantities. The same result would

have been secured if the hypoglycemia was due, for example, to diminished secretion of the diabetogenic substance of the anterior pituitary. The hypoglycemia produced experimentally by extirpation of the anterior pituitary may be alleviated by complete removal of the normal pancreas. By this means two endocrine factors influencing the production and utilization of sugar in opposite directions are balanced at a new and lower level.

The signs of hypoglycemia have been frequently described. Attention has been drawn from time to time to chemical substances, the accumulation of which was thought to be responsible for these signs, but further study has failed to support the early observations. There is no convincing evidence that a toxic chemical substance accumulates when the blood sugar is maintained at low levels. The typical signs of profound hypoglycemia are dependent on the loss of integrity of nerve cells in the higher centers of the brain. There are no physical signs of hypoglycemia in the spinal animal or in one anesthetized by a general anesthetic.

CHEMISTRY OF INSULIN

The most active form of insulin is that obtained in the crystalline form (Abel).¹⁰ This material is composed of numerous amino acids (cystine, tyrosine, arginine, histidine, lysine, leucine, glutamic acid, proline and phenylalanine) and gives all the typical protein tests. It appears very unlikely that the active material is merely adsorbed on the crystalline protein. Recent work by Scott¹¹ has shown that the crystals are probably the salt of insulin with a metal such as zinc or cadmium. The free substance has not yet been obtained in crystalline form.

STANDARDIZATION

The potency of insulin is expressed in terms of the international standard powder, which contains 8 units per milligram. The crystalline preparation, which has a potency of approximately 25 units per milligram, is being substituted for the amorphous material. There will be no change in the size of the unit. Insulin should always be tested against the international or subsidiary standard. The lowering of blood sugar in rabbits or the production of convulsions in mice furnishes satisfactory effects of the hormone for the comparison of unknown and standard products.

SUBSTITUTES FOR INSULIN

Insulin therapy has two obvious disadvantages (1) the transient effect and (2) the necessity for parenteral injection of the active material. The most important of the suggested substitutes is synthalin (decamethylene diguanidine). This substance does not increase deposition of muscle glycogen and the effect on hepatic glycogenesis is accomplished in a highly unphysiologic manner. Insulin is apparently the only agent that inhibits sugar formation without damaging liver cells. Extensive deposits of fat produced in diabetic dogs by fat feeding as well as by many chemical compounds other than synthalin interfere with sugar formation. It is preferable for the diabetic organism to excrete the large quantities of sugar made by a relatively healthy liver than to be made "sugar free" by damaging liver tissue so that less dextrose is formed.

THE INFLUENCE AND THERAPEUTIC USE OF HEAT

PHYSIOLOGIC EFFECTS OF HEAT

RALPH PEMBERTON, M.D.
PHILADELPHIA

The use of external heat in the sense ordinarily understood by that term was a familiar therapeutic procedure to the ancients of Greece and Rome, who constructed elaborate establishments for the practice of hydrotherapy in various forms and also made use of naturally occurring thermal springs, such as those still frequented at Aix les Bains. Notwithstanding the application of heat to an increasing variety of conditions, the manner in which it accomplishes its purpose has been, until recently, poorly understood, chiefly owing to the fact that the actual conduct of most physical therapeutic measures has been in the hands of persons untrained in medicine.

One of the outstanding phenomena, obvious even to the layman, in the systemic application of external heat is the more or less profuse sweat induced. This occurrence has given rise to the popular idea of "elimination," which has found great favor with the public and has even crept into medical writings in an uncritical way. The conception of what is eliminated has been vague, and small account has been taken of other and equally important changes induced. The last few years have been productive of new data however and, while much remains to be investigated, a fairly clear concept is now afforded of what occurs in the physiologic sense when the human body is exposed to heat.

According to Bazett,¹ radiant energy, to which the body is normally more or less exposed in the form of sunlight and also, in recent years, through artificial means, may be classed as (a) ultraviolet rays of short wavelength, 1,850 (artificial light), 2,900 (sunlight) to 3,600 angstroms, (b) visible light, from 3,600 to 7,500 angstroms, (c) near infra-red, from 7,500 to 15,000 angstroms, (d) intermediate infra-red, from 15,000 to 30,000 angstroms, and (e) far infra-red with wavelengths greater than 30,000 angstroms. Heat from radiating objects, such as steam or hot water radiators, hot water bottles and hot water baths, consists mainly of group e, and transmission to a depth is by conduction, when derived from sources such as lamps with a dull red glow, the main energy is probably in groups d and e, and conduction is still the main method through which deep effects may be attained. However, if sunlight or luminous sources of heat are employed, much of the energy may be in groups b and c and some deep effects will result through direct transmission of the radiant energy to a depth.

According to Bazett,² the rate at which changes of temperature penetrate is relatively slow, the heat capacity of the tissues is high, and relatively large quantities of heat have to be transported before the temperature is greatly altered. The tissues can be warmed, however,

up to a temperature of 98.6 F with relative rapidity, venous blood in its return carries heat inward and does so the more rapidly the greater the extent of the vasodilatation, in addition, the increased arterial blood supply warms the tissue at the expense of the rest of the body.

In a cold environment the conditions are simpler, but the thermal conductivity is diminished as the result of the vasoconstriction induced. Zondek³ reported that an icebag in close apposition to the thigh caused a fall of temperature at a depth of 50 mm from 98.8 to 97.3 F in one hour when the skin had fallen to 44.6 F in a subject with fat 25 mm thick. In the case of a fat subject (fat 50 mm thick) an icebag applied to the abdomen for one and one-half hours caused a fall of the skin temperature to 42.8 F, but the temperature of the abdominal muscles at a depth of 50 mm fell only from 99.7 to 96.8 F.

In his study of the effects of abdominal thermal applications on the dog's intraperitoneal temperature, Brill⁴ observes that cold applications have little effect on the intraperitoneal temperature, the greatest fall noted being 2.5 degrees C, which was observed in one instance. Hot applications likewise produce no appreciable change. Such observations as these, which have been corroborated by Hepburn, Eberhard, Ricketts and Rieger,⁵ strongly suggest that the beneficial effects of hot and cold abdominal applications are due to factors other than the effect on intraperitoneal temperature.

The effects of systemic exposure to heat from various sources are much the same in principle and will therefore be discussed together, except when certain differences necessitate particularization.

One of the earliest effects to be noted after systemic exposure to heat is that on the circulation. Thus, the pulse rate rises more or less proportionately to the rise in body temperature⁶ in the ratio of about ten beats for 1 degree F,⁷ much as it does in fever.

The effects on blood pressure of external heat and cold are somewhat varied.⁸ Some observers believe that all baths at a temperature much above or below that of the body raise blood pressure,⁹ but in general in normal persons warm baths probably tend to lower blood pressure and cold baths tend to raise it. There are some exceptions to this rule, and a bath above 40 C (104 F) may give a blood pressure above normal, while a cold bath may occasionally induce a temporary fall in blood pressure preceded and followed by a rise.⁷ If exposure to external heat is in the form of a bath, there takes place, in addition, a diuresis dependent on the immersion of the abdomen in the water.

Systemic exposure to external heat generally produces a more or less well marked hyperpnea or over-ventilation of the lungs. This increases roughly parallel with the rise in body temperature, and water vapor is lost in large quantities through the expired air. Systemic exposure to heat in any form results, therefore, in a loss of fluid from the body through the lungs and sweat and, following baths, through the urine also. This causes a temporary loss of weight.⁷ Following

extreme sweating a slight concentration of the blood ¹⁰ tends to arise, but it is doubtful whether this takes place in any important degree under the usual conditions of clinical practice ¹¹

Next to the kidneys the skin is, in man, the most important accessory channel for the elimination of water, and the salt excreted in the sweat may amount to ten times that normally present in the feces ¹² The sweat also contains, qualitatively, certain other substances occurring normally in the urine, such as urea, ammonia, uric acid, amino acids, creatinine, phosphates and sulphates, ¹⁰ and it may also contain dextrose The elimination of these substances, especially water, salt and urea, forms the basis of the long-standing use of the sweat process in various forms of nephritis accompanied by edema or high blood urea nitrogen There has been wide clinical belief in the value of this measure in nephritis, in which its influence is undoubted as regards salt and water As regards the compensatory elimination of nitrogenous substances, there is some evidence to indicate it, but there are those who doubt "vicarious" excretion of nitrogen on the part of the sweat glands, and it seems that perspiration does not always lead to a decrease of urea in the urine ¹³

It is not generally appreciated that carbon dioxide, a chief end-product of metabolism, escapes through the urine and sweat, as well as through the lungs, and one of the most fundamental effects of exposure to heat appears to depend somewhat on the increased loss of carbon dioxide through these three channels As a result of the rise in the body temperature or hyperpyrexia, the general body metabolism is increased and carbon dioxide is formed in quantities larger than normal The overventilation through the lungs, however, washes out the carbon dioxide in even greater proportionate amounts There also results from the heightened metabolism an increase in the phosphates and sulphates from the breakdown of protein, but these acid substances find their escape through the urine In addition to the loss of all these substances, it has also been shown that the urine and the sweat contain fatty acids, including lactic acid, which are probably increased in amounts during exposure to external heat The elimination of lactic acid through the skin during the sweating process constitutes one of the significant factors in the maintenance of the acid-base equilibrium in the body Because of the low degree of ionization of lactic acid, the excretion of lactic acid and lactates results in the sparing of fixed base ¹⁴ The sweat produced under the influence of heat, induced by the radiotherm in the cases studied, contains lactic acid in concentration greater than that of the blood

The net result, therefore, of the loss of these various acid substances, chiefly carbon dioxide, is to leave a relative excess of alkali in the blood and probably in the tissues ¹⁵ The blood becomes too alkaline, a systemic alkalosis results, and the excess of alkali is then eliminated through the urine and sweat until the normal acid-base equilibrium is restored The urine and sweat

thus generally change their reaction, becoming less acid, alkaline, or more alkaline A sustained alkalosis may lead to tetany, it constitutes one of the sources of danger in the improper therapeutic use of external heat ¹⁶

A great loss of water and salt consequent on exposure to heat induces serious consequences unless this loss is partly compensated by ingestion This loss may be one of the factors, together with the alkalosis referred to, which induce the severe cramps in the muscles occasionally seen among stokers and other workers in extreme heat The clinical application of external heat with excessive sweating may likewise be followed by serious consequences Water is usually given to the patient, and saline solution is occasionally administered to compensate for the losses of fluid and salt It is obvious however that, unless the temperature and amounts of fluid are considered, the anticipated sweating and the benefits of it may be prevented or delayed

The physiologic changes induced by local exposure of a part to heat are along the lines just described, but more intensive treatment is obviously possible because the process can be longer continued Relaxation of tissues is induced, especially of the muscles, together with a hyperemia probably due to dilatation of blood vessels and a greater total blood flow in the area concerned Another physiologic factor involved is the increased rate of transfer of fluid across the capillary wall during the vasodilatation induced by heat, as shown by Gibbon and Landis ¹⁷

Local sweating also takes place, and the tissues are put in a condition to benefit more than they otherwise would by such measures as massage and passive motion or even active motion If the local use of heat is continued too long, a systemic response may take place, dependent on a general hyperpyrexia comparable to that following systemic exposure This may be an advantage or a disadvantage, according to the conditions present, but must be considered in feeble patients or those already being exposed to systemic heat The effects of heat locally will be further developed under the local use of heat in surgery

A recent development in the use of heat is the artificial induction of fever A variety of measures is useful to this end, namely, those already mentioned and those depending on exposure of the body to radiation, to induced electric fields and to the actual passage of the electric current through the tissues The measure last mentioned is that which has been most fully studied

Another means of producing much the same result is the injection into the body of material such as killed bacterial organisms, foreign proteins and the like, the reaction to which includes the production of fever It is probable that the results achieved by these several respective measures, however, depend largely on common factors for their effects The use of hyperpyrexia through diathermy ¹⁸ permits rather more controlled study of the conditions arising and is in other ways preferable in a majority of cases suitable for such therapy The alterations of physiology achieved through it include, apart from the usual results of external heat, the change in the blood formula recognized to accompany the use of nonspecific protein reactions, as well as some other phenomena referable to disturbances of the nervous system and even of the renal system brought

about through the higher and more sustained febrile state. The kidney occasionally experiences detriment, under vigorous applications, and this may result, in part, from damage to it by the high temperatures immediately adjacent to the organ itself. Similar considerations apply to the use of ultra high frequency induced electric fields which cause eddy currents in tissues with resultant heating effects. This procedure permits of deep penetration and can be used locally or systemically. It has the added advantage of obviating immediate contact with the patient.

The treatment of disease by means of hyperpyrexia originated with the use of the malarial parasite in dementia paralytica and has been extended to include a considerable variety of disease states. Omitting discussion of the therapeutic effects on diseases of the central nervous system, which will be considered elsewhere, the diseases chiefly submitted to this form of therapy have been various forms of arthritis and asthma.

The treatment of disease states by raising the body temperature through various electrical means is a powerful therapeutic measure capable of real benefit and also of undoubted harm unless carefully controlled. At the present time, therapy of this nature should be conducted under hospital auspices.

FORMS OF APPLICATION

Dry Heat—The various means and methods of applying physical therapy in almost any of its forms constitute specialties in themselves, and within the small compass of the present article only those features can be considered which are essential to a general understanding of the subject.

Apart from the familiar hot water bag, the most common mode of application of dry heat is that afforded by the electric light bulb. For local application, the apparatus usually takes the form of a parabolic mirror, suitably mounted, with the lamp at the focus so that the issuing rays are parallel. The apparatus can be held in the hand, or it is mounted on a stand and can be directed toward any part. For more intensive local use a boxlike container, with or without an internal reflecting surface, open at the ends and equipped with light bulbs, is placed over the limb or part, with the patient in the sitting or the reclining position.

For systemic exposure, lamps are usually placed within a "cabinet" or large box containing a reflecting interior surface and large enough to allow the subject to sit on a chair, the head emerging through the doors or other covering at the top. The number of lamps in such an apparatus may be from twenty to fifty or more, subject to control in small groups. For exposure in the recumbent position, the lamps are placed within a troughlike semicircular container, also bearing a reflecting interior surface and about 5 feet in length. This is placed, with the concave side down, over the subject, whose head is allowed to emerge at one end. Blankets are placed over the whole and drawn snugly around the neck and face in order to prevent undue radiation.

Dry heat is also administered in the form of hot air, but this usually requires elaborate equipment for the purpose of heating the air and is hardly available to the general practitioner, except in a few institutions. Electrical resistance coils placed within a boxlike container also afford a useful means of obtaining dry heat, especially for application to limited areas such as a knee or an ankle. These various forms of apparatus can all be obtained on the market under various trade names,

and they can be improvised at home with excellent results when necessity demands. Dry heat of lesser intensity can also be supplied for local purposes in the form of a resistance coil of flexible wires, properly insulated and covered with cloth, for such uses as those to which the familiar hot water bag is put.

One of the most important uses of dry heat in a local sense is that afforded by the actual cautery, which may be heated by flame or fire, as in the old days, or, more appropriately, by the electric current. The chief use of this is for destructive purposes in dermatologic conditions, including new growths, and will be discussed under that heading. The actual cautery has also long been used as a "counterirritant" in sciatica, though less so now than formerly. Probably some of its effects are due to the reaction from protein split products and the "shock" of the burn.

Hydrotherapy—Probably the oldest form of the systemic application of heat is the hot bath. The presence of thermal springs scattered throughout the world has given rise to elaborate establishments for their utilization, but as far as heat per se is concerned almost equally satisfactory results can be obtained in many instances by the simplest forms of apparatus, such as the ordinary bath tub. The water used may be pure or it may contain various salts or other substances, such as magnesium sulphate or carbon dioxide, intended to increase or add to the effects. The temperature of the water varies, of course, according to the purpose of the bath, and this question will be considered under therapeutic indications.

Next to the hot bath, the most frequently employed form of moist heat is that afforded by the so-called hot pack. This consists in principle in wrapping the body in a sheet or blanket made hot by being dipped in hot water of about 82 C (180 F) and subsequently wrung out more or less thoroughly. Obviously the severity of application will depend on the temperature of the enveloping sheet or blanket, and this effect will be further influenced by the number of blankets superimposed on the subject to prevent evaporation and cooling. Occasionally, the sheet or blanket placed on the body is below body temperature, constituting the "wet pack," under which circumstances the effect of heat is achieved through a conservation of the body heat by wrapping the subject with many blankets to prevent as much evaporation as possible.

Another form of exposure to moist heat is the steam bath, although this is by no means so widely employed as the hot water bath. A home-made apparatus can usually be "rigged up" in any household by means of large steam kettles, an oil lamp and a frame to elevate the bedclothes. The steam "room" has long been in use and consists simply of a chamber into which steam under low pressure is allowed to escape. The disadvantages here are that the patient must breathe the hot moist air, and a better form of application is that in which the subject sits in a cabinet or lies in a sort of box with his head outside. There is some danger, however, in this procedure, as burns have occasionally been caused by faulty steam pipes or joints. In some instances, electric resistance coils supply steam under low pressure in a manner well adapted to this purpose.

The mud bath is an old form of application of moist heat but, in general, depends on the availability of certain soils, heated by thermal springs or artificially, and need hardly be considered at length here.

The forms of wet heat that have been described are used chiefly for systemic treatment, but a useful local application of moist heat can be made by means of the so-called whirlpool bath. This consists of a receptacle of suitable shape, usually deep and rather narrow, containing warm or hot water made to circulate rapidly by means of a laterally placed water jet. The part to be treated, usually an arm or a leg, is placed within the receptacle, and the temperature of the water is gradually raised to the desired point. The motion of the water intensifies the effect of the heat for any given temperature and has other advantages through its impingement on the tissues.

THERAPEUTIC INDICATIONS AND PRACTICE

The therapeutic indications for the use of external heat can be grouped under the two general headings of general exposure and local exposure, according to whether a systemic or a local effect is desired. Systemic effects find their application for the most part in medical, as contrasted with surgical, conditions and have been widely used in the following disease states or syndromes: nephritis, acute or chronic, arthritis and rheumatoid conditions, in which either local or systemic heat or both may be used, and neurologic conditions, including neurasthenia, functional psychic disturbances and the true insanities.

The therapeutic indications for the use of heat locally are chiefly in the following fields: surgery, especially orthopedic, following fractures, dislocations, sprains, cicatrization after operative procedures and the like, and arthritis, when a limited influence on a joint or joints is desired.

NEPHRITIS

There is probably no other condition in medicine in which the systemic use of external heat has been longer thought to have consequences of value than that of nephritis. Whatever other pathologic manifestations may accompany nephritis, certain symptoms demanding treatment are apparently dependent on the retention of toxic material, possibly of a nitrogenous nature, salt or water, and acid products of metabolism, especially phosphates and sulphates.

As already pointed out, some workers doubt the vicarious removal of nitrogenous substances through the skin, when elimination through the urine is reduced, but clinical experience is in favor of the view that something of this nature may occur. Furthermore, it is possible that some other toxic substances the nature of which is not yet known may be removed at the same time. It is well recognized, however, that the degree of toxicity does not run precisely parallel with the accumulation of nitrogenous substances. Thus, patients with uremia may show a disproportionately small rise in the urea nitrogen and, on the other hand, patients with marked increase in the urea nitrogen may present few or no clinical evidences of intoxication. Again, the figures for the "urea clearance" test may fall as low as 20 to 40 per cent in the presence of a normal blood urea.¹⁹ It is safe to say, however, that in nephritic conditions accompanied by marked laboratory evidences of retention of nitrogen, or by clinical evidences which suggest the toxemia consequent on such retention, the sweating process is to be considered. There is some

evidence that in conditions accompanied by retention of blood nitrogen the sweat may contain nitrogen in amounts larger than normal.²⁰

The argument has been advanced that, in the presence of toxemia from renal insufficiency and retained nitrogen, sweating serves only to concentrate the blood and to add to the danger from the retained substances.²¹ There is some doubt as to the validity of this, however, as the blood maintains its water balance with great tenacity, drawing on the tissues for this purpose, and the evidence is not final that under conditions of ordinary therapeutic procedure the blood undergoes any true concentration.⁸ Furthermore, in the absence of inability to excrete water there would seem to be no objection to the administration of fluid to prevent concentration, as is indeed the practice in many hospitals. It is to be borne in mind, however, that the elimination of water constitutes one of the functions of the kidney, and, as O'Hare²² points out, a further burden may be added and even pulmonary edema may arise from undue administration of fluids.

Finally, it should be stated that the results believed to be achieved may be due to changes induced by heat in the blood flow, to an alteration of metabolism, or, in nephritis accompanied by acidosis, to the production of a systemic alkalosis as already described. Whatever the mechanism and whatever the difference of opinion as to the theoretical benefits to be obtained, however, it is probable that some experienced clinicians would be unwilling to withhold application of the sweat process as a practical method of treatment in the toxic nephritis under discussion.

Another phase of renal dysfunction in which the sweat process has long been regarded as of value is that accompanied chiefly by retention of salt and water. While the bowels may be made the channel for elimination of water in large quantities by hydragogue cathartics, water can be eliminated in equal or even greater amounts through the sweat. Evidence has been presented that salt may be removed through the sweat channels in amounts equal to or larger than those occurring in the feces.

In the presence of edema or anasarca of renal origin, the hot pack or general body bake may at times have significant consequences and the loss of fluid from the tissues may be obvious almost from the start. Usually, however, many treatments are required.

The practice of giving sweat baths in nephritis is less common than formerly. The modern view of therapy in chronic Bright's disease is directed toward the elimination of toxins which, in passing through the kidney, may aggravate the renal lesion. This means the eradication of infection, proper elimination from the bowel, and finally a diet so devised as to avoid undue strain on the renal system by all products of excretion. This, of course, may include the ingestion of water. It would appear that proper adjuvant use of the sweat channels would be complementary to the foregoing procedures, but the problem is fraught with many difficulties that have not been wholly threshed out.

In all these conditions the physician must be guided by good judgment in the application and severity of the measures used. The guiding principle must be

19 Beaumont, G. E. and Dodds, E. C. *Recent Advances in Medicine*. Philadelphia: P. Blakiston's Son & Co. 1934, p. 49.

20 Cajon, Crouter and Pemberton. *Ann. Int. Med.* 2:1243 (June) 1929.

21 *Textbook of Medicine*, edited by Cecil R. L. and Kennedy Foster. Philadelphia, W. B. Saunders Company, 1927.

22 O'Hare, J. P. *The Treatment of Chronic Bright's Disease*. J. A. M. A. 103:1373 (Nov. 3) 1934.

that benefit can be forthcoming only when the patient is in a position to withstand treatment of such severity and respond to it, and the physician must be on his guard lest contraindications appear, such as cardiac decompensation, circulatory collapse or high fever. It is sometimes necessary, however, to push treatment even in the presence of such contraindications.

The particular manner in which heat is systemically applied in nephritis is of secondary importance, but the simplest form, and one that can be carried out in any household, is the hot pack already briefly mentioned. This properly comes under the topic of hydrotherapy, however, and the further details of its application will be discussed there.

Considerable prostration may occasionally follow the general procedure referred to, and, furthermore, although the effect of any one "bake" may be inappreciable, the effect of many treatments is sometimes cumulative. In few diseases is any single measure to be regarded as the only one to be relied on, and this is eminently true of the use of the sweat process in nephritis. The use of the skin as an emunctory organ must be accompanied by full use of the other channels, especially the bowels, and by such medication and control of protein, salt and fluid intake as modern conceptions of medicine require.

The systemic application of heat is beneficial in meeting the conditions generally included under the head of shock. In this connection mention should perhaps also be made of the use of the mustard bath or the mustard pack, especially in relation to collapse in infants. Some clinicians²³ believe that there is no medicinal agent, with the exception of epinephrine, which is so dependable. The water should approximate 105 F, and mustard should be added in the amount of a heaping tablespoonful to each quart of water. Care must be exercised to protect the eyes of the patient, and constant friction should be maintained while the subject is in the tub. Baths of this general nature are useful also in relation to the convulsions which children experience, but this subject properly belongs under the use of heat in diseases of the nervous system.

Heat in the form of hydrotherapy has long constituted part of the process known under the name of the Nauheim bath, extensively used at Nauheim, Germany, in relation to cardiac disorders of various kinds. The temperature of the water begins at 92 F, and the measure in general can therefore be properly placed in the category of systemic heat. The benefit to be derived by the Nauheim bath is a matter over which there is much difference of opinion. The beneficial consequences alleged to arise have been referred to the carbon dioxide content of the water and also to the friction employed while the subject is in the bath, as well as to various other factors, such as rest and change of scene.

It must be confessed that the favorable clinical evidence adduced by those who have the greatest familiarity with this form of treatment is considerable, and it is also only fair to say that the conditions which obtain at Nauheim cannot necessarily be duplicated elsewhere through the use of artificial baths of the same general nature.

This form of treatment has never had very wide use in the United States, and it would profit by further study at the hands of disinterested observers.

ARTHRITIS AND RHEUMATOID CONDITIONS

The field in which the application of external heat, both systemically and locally, has its most extensive and varied application is probably that of arthritis and rheumatoid conditions. The full benefits to be derived from the systemic use of heat in this connection are not always forthcoming from the heat alone, however, and sometimes depend on contrasting and accessory applications of cold. The latter phase of treatment constitutes an essential part of hydrotherapy, and the details of the conduction of this measure in its various forms will be considered in the section devoted to that topic. The matter will be discussed here sufficiently merely to indicate the general application of heat to the rheumatoid syndrome.

In view of the considerable confusion that still exists regarding the nomenclature and classification of the arthritides, as well as of the underlying pathologic changes concerned, there is no stereotyped guide to be followed in selecting cases appropriate for this treatment.

Those patients who are fairly robust afford the best opportunity for this practice. It is important to remember that systemic exposure to heat in any form may occasionally have distressing consequences, either immediately or after a course of treatment, and it is therefore essential to exercise caution in subjecting to such treatment patients who are ill equipped to stand it. Those forms of arthritis which are thought perhaps to withstand such therapy best and to benefit most from it are cases of the degenerative or so-called hypertrophic type in middle aged, well nourished women, although the proliferative or so-called atrophic type may be equally helped. It must be pointed out here, as in connection with nephritis, that exposure to heat or hydrotherapy constitutes only one measure of treatment in the rheumatoid problem and must not be followed except in correlation with other established principles of treatment. Especially is this true in relation to the important influence of focal infection. A patient with arthritis should not be subjected to the measure under discussion unless and until a complete medical examination has indicated the justifications and indications for it. For generations the public has frequented sanatoriums of all kinds where these measures have been applied in a wholesale way with the result that, although these measures have undoubted therapeutic value, failure and detriment also have followed.

As mentioned in the section on physiology, belief in the value of "elimination" in this disease has long been popular, but there is only limited evidence to support this as an important factor in itself. Elimination of water²⁴ in the form of sweat may in itself contribute to a betterment of the disturbances of physiology accompanying the rheumatoid state. The possibility that a low-grade "edema" of some tissue accompanies certain phases of the arthritic syndrome cannot be dismissed from consideration. There is, however, definite evidence that some of the other effects achieved by exposure to heat play an important role in the treatment of arthritis. These effects are chiefly those arising from the heightened circulation and the increased metabolism induced. Evidence of changes in the circulation is to be seen in the obvious influence on the skin capillaries of the contrast baths or douches so success-

²³ Ward J B Arch Pediat 45 556 (Sept.) 1928

²⁴ Pemberton Ralph and Scull C W M Record 140: 653 (Dec 19) 1934

fully used in institutional treatment at the conclusion of the "bake" or hot bath. A true "metabolic whip" is afforded by cold water properly used.

This procedure has application to a variety of debilitating conditions, thus, Knopf in his "Report to the United States Government on Tuberculosis with Some Therapeutic and Prophylactic Suggestions," expresses the opinion that a judicious course of hydrotherapy is of value in helping to "strengthen the cutaneous and nervous systems against the changes of temperature" and has prophylactic value toward the development of "colds" among certain classes of tuberculous patients.

The "bake" or bath may be given alone, however, in which case profuse sweating is induced and the subject is allowed to rest for an hour or more to compensate for the somewhat debilitating effects, or, more frequently, the exposure to heat is briefer and sufficient only to inaugurate or induce a mild diaphoresis. Following this procedure, which is generally administered with the patient in a sitting posture, a "tonic" shower or douche is given, beginning considerably above body temperature and shortly reduced to slightly below body temperature. This is best accomplished by an attendant who directs on the patient a jet of water, the temperature of which is under control. An exposure of about eight minutes to the electric cabinet "bake," followed by a so-called scotch douche or other form of cooling hydrotherapy, permits the subject to go at once out into the air with a sensation of exhilaration and well being instead of lassitude. There is also exercised at the same time an influence on the nervous system, which in the end may be quieted by the process described, notwithstanding the apparent "shock" of the cool or cold water. Even persons of robust constitution should be subjected only gradually to these procedures, but by beginning cautiously even highly asthenic types can be educated to stand them and be benefited by them.

The sweating process alone, without the cooling contrast shower, is easier of attainment and can be brought about by means of the hot pack or hot bath in almost any household. In many instances the metabolic stimulus given by this single procedure is of great value and should be utilized when circumstances justify it. Some of the effects of cooling hydrotherapy can be achieved by means of the bed sponge or bath, but care must be used to avoid chilling. If the sweating process is prolonged and perspiration is profuse, the patient must rest for an hour or more before rising, or depletion and fatigue will result.

The general regimen briefly outlined can be carried out more or less successfully in the home, but the full achievement there of such results as follow the conduction of these measures by skilled hands in adequately equipped institutions can hardly be expected.

Much of the benefit of treatment at institutions is made possible by the incidental removal of the patient from causes of worry and fatigue, and to this can often be added the stimulus of new surroundings.

Some further mention must be made of the influence of induced fever,²⁵ probably most conveniently achieved in the rheumatoid syndrome through diathermy. The whole subject of the influence of induced fever on various disease states is still far from being thoroughly understood, and this limitation applies equally in respect

to the treatment of arthritis by means of it. There is some evidence to indicate, however, that in certain phases of the arthritic syndrome, especially perhaps the more acute states, beneficial results may follow the induction of sustained fever up to 104 or even 106 F. Differing uses of nomenclature as well as uncertainty as to diagnosis make it difficult to attach finality to the value of the beneficial results reported to date. Gonorrheal arthritis has also been reported, on more substantiated evidence, to be benefited. In view of the varied etiology of arthritis, however, conservatism should be exercised in applying this potent measure indiscriminately to large groups of cases, in that many of them are asthenic and poor candidates for radicalism of any sort.

LOCAL APPLICATION OF HEAT IN ARTHRITIS

The application of external heat locally to a joint or joints in arthritis is often of the highest value. The principle obtains here, as elsewhere, that reliance must not be placed on this measure alone. It must be considered in conjunction with other principles of treatment of the disease as a whole, and the joint in particular. The measure most often used in conjunction with local external heat in arthritis is massage and, although often misused in ignorant hands, it constitutes an almost necessary adjunct to the use of heat alone, especially in the form of effleurage. The forms of heat available for local use are discussed at the beginning of this article. The value of the heat can sometimes be enhanced by incorporating with it some other principle, as in the use of a hot saturated solution of magnesium sulphate applied to the affected part and kept hot by repeated application or a radiant lamp. This procedure sometimes greatly relieves pain. Application of heat should not be carried to the point of irritation and should depend for its effects on repeated use, once or twice a day, over a period varying from about ten minutes to half an hour. The temperature within the apparatus should not be above about 82 C (180 F), or the duration of treatment greater than twenty minutes at the outset. Temperature and length of exposure can be slowly increased. Local sweating generally occurs, and the part should be kept warm after the treatment. If a region such as the shoulder is baked for a long period, a systemic reaction may occur comparable to that following systemic exposure, the results of which may be depleting or otherwise undesirable.

Heat is of value also in disturbances of circulation in the peripheral vessels, such as thrombo-angitis obliterans, diabetic gangrene, Raynaud's disease and intermittent claudication. Heat has been recommended systemically²⁶ in thrombo-angitis obliterans to control pain but can be more conservatively used locally.

In advanced peripheral vascular diseases, Starr²⁷ recommends heat at an "optimal temperature" in conjunction with rest, desiccation and exposure of the part to oxygen. A temperature of from 33 to 35 C usually relieves pain and is preferable to less controlled variations.

There may also accrue a beneficial effect on the indolent lesions often encountered in such conditions. Coincident care of the underlying state is of course imperative. Contrast baths may have value when the local vascular function permits.²⁸

BURDICK SHORT WAVE DIATHERMY MACHINE (SWD-5) ACCEPTABLE

Manufacturer The Burdick Corporation, Milton, Wis

This unit is recommended for medical diathermy as used for producing heat within the body tissues, and for surgical diathermy. The apparatus is available in either cabinet or portable style. The machine is of the single tube, simple oscillating type. Raw alternating current is fed into the plate circuit and thus only the positive half of the alternating current 60 cycle is used. Proper tuning to resonance, in conjunction with the relative power output of the patient's circuit, is indicated by a milliammeter of the thermocouple type. A protective circuit breaker switch is provided to guard the vacuum tube oscillator against injury to excessive variations in line voltage and line surges.

Under full load this unit was operated for two hours and the temperature of the cabinet and transformer did not rise above the limits of safety previously established by the Council. The wavelength was found to be approximately 15 meters. The input power is about 386 watts. So far as it is known, there is no reliable or acceptable method of measuring the output power of short wave diathermy machines.

The machine was tested in a clinic acceptable to the Council and the investigator reported that the unit supplied sufficient energy to heat the body tissues whenever such treatment is indicated. The tissue heating effect in the human thigh was investigated. The technic was that recommended by the manufacturer. Cuff electrodes about 20 inches long and 3 inches wide were used, one wrapped round the thigh proximally to the knee, and the other one close to the hip. When they are applied to the patient, the rubber cuffs are separated from the skin by one-eighth inch felt and one thickness of toweling.

Burdick Short Wave Machine.

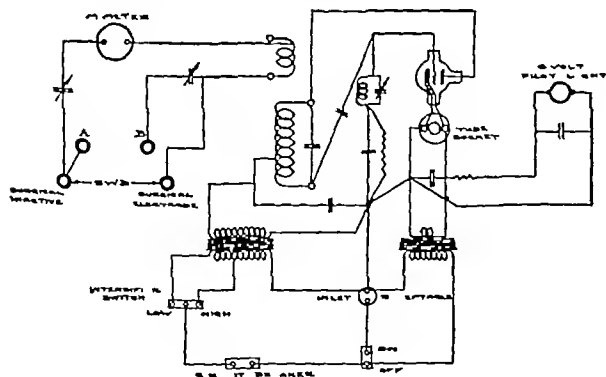

Diagram of circuit

This technic was used throughout the tests. Thermocouples were introduced into the subcutaneous deep lying tissue (quadriceps extensor).

After twenty minutes treatment the machine being operated at the patient's tolerance the temperature rise (average of seven tests) was observed to be more than that for conventional diathermy using two electrodes one on the medial and one on the lateral aspect of the thigh.

Electrosurgical investigations were carried out by the investigator in his clinic. The performance and efficacy of the surgical currents generated by this machine were reported to meet the standards expected by the Council.

Burns may be produced by this machine, but with ordinary care they may be avoided, their likelihood to occur is much less than with conventional diathermy.

In view of the foregoing report the Council on Physical Therapy voted to include the Burdick Short Wave Diathermy Machine (SWD-5) in its list of accepted apparatus.

Council on Pharmacy and Chemistry**PRELIMINARY REPORT OF THE COUNCIL**

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING PRELIMINARY REPORT
PAUL NICHOLAS LEECH Secretary

ACETYL-BETA-METHYLCHOLINE AND MECHOLYL (MECHOLIN)-MERCK

Under the name Mecholin, the firm of Merck & Co, Inc., recently submitted to the Council its brand of acetyl-beta-methylcholine. Subsequently the firm informed the Council that, on account of possible trade mark interference it was obliged to give up the name 'Mecholin' and that it would suggest the name 'Mecholyl' instead. The question of the firm's right to the use of a proprietary name has not yet received definitive consideration by the Council. Any decision that the Council might reach in this matter would apply as well to the name 'Mecholyl' as to the originally proposed name. The Council has voted that the product be not accepted until more extensive clinical studies have been made. In considering this product the Council decided to publish an article on acetyl-beta-methylcholine in the form of the following preliminary statement.

The numerous investigations on acetylcholine have indicated that its action resembles that produced by stimulation of the parasympathetic nervous system but in addition causes dilatation of blood vessels which are not known to be innervated by parasympathetic nerves (limbs, for example). Indeed, there is considerable evidence that acetylcholine is identical with, or at least similar to, the intermediary substance liberated by parasympathetic stimulation, and capable of exerting an action on structures in the body which are distant from the stimulated nerves (Hunt and Taveau¹, Dale², Loewi,³ Babkin, Gibbs and Wolff,⁴ Gibbs and Szelöczy,⁵ Feldberg and Rosenfeld⁶). On the mode of liberation or formation of this intermediary substance in the body, practically nothing is known.

The widespread distribution of choline in the organism has been shown by the many workers who have investigated the problem since Strecker's⁷ original isolation of this base from bile in 1849. Since choline is a product of the hydrolysis of phosphatides, it is found wherever lecithins occur.

The demonstration of the presence of free acetylcholine in the tissues is attended by numerous difficulties. Whether appreciable amounts exist in any tissues other than those of the spleen, placenta and adrenal medulla appears, at the present time, exceedingly doubtful (Dale and Dudley,⁸ Chang and Gaddum⁹, Minz¹⁰, Feldberg and Minz¹¹). It is of interest that Hunt¹² as early as 1899 discovered choline in adrenal

extracts Shortly after he was able to demonstrate that the extract contained a substance which readily yielded choline on chemical manipulation¹⁸

Kapfhammer and Bischoff¹⁴ reported the isolation of considerable amounts of acetylcholine from oxblood, and Vogelfanger¹⁵ and Parnas¹⁰ have confirmed their observations. The work of Dale and Dudley,¹⁷ Dudley,¹⁸ Wrede and Keil,¹⁹ Strack, Neubaur and Geissendörfer,²⁰ Chang and Gaddum,⁹ and Gollwitzer-Meier,²¹ however, makes it appear likely that the acetylcholine found by Kapfhammer did not exist as a free substance in the tissues but was formed in the process of the isolation. Strack and his co-workers found that, whereas fresh liver tissue contains practically no free choline or acetylcholine, rapidly increasing amounts of free choline are formed after the circulation is interrupted. They think it not unlikely that the acetylcholine isolated by Kapfhammer arose through the esterification of phosphatides

PHARMACOLOGY

The pharmacologic actions of acetylcholine comprise two groups (1) The 'muscarine' or 'parasympathetic' action and (2) the 'nicotine' action. The 'muscarine' action is shown by the inhibitory effect on the heart, the vasodilator effect with an accompanying lowering of the blood pressure, and the stimulation of gastric and intestinal peristalsis. All these effects can be prevented or abolished by atropine.

The 'nicotine' effects are less conspicuous and are usually masked by the parasympathetic effects unless these are prevented by a preliminary dose of atropine. They are due to stimulation of sympathetic ganglions and result in a considerable rise in the blood pressure. While all derivatives of acetylcholine show essentially the same pharmacologic actions, they do so in varying degree. Hunt and Taveau²² in 1911 made an extensive study of various compounds of acetylcholine and found that acetyl-beta-methylcholine (trimethyl-beta-acetoxy-propyl-ammonium chloride) possesses marked 'parasympathetic' actions and practically no 'nicotine' actions. These observations were recently confirmed by Simonart²³. Menge²⁴ found that this substance is much less readily hydrolyzed to the less active substance choline than is acetylcholine. Acetyl-beta-methylcholine was first prepared by Taveau²² and by Menge²⁵ and was studied pharmacologically by Hunt²⁶ and by Hunt and Renshaw²⁷.

These studies have been extended by a group of workers at the University of Pennsylvania. Comroe and Starr,²⁸ in a series of experiments on animals, have confirmed Hunt and Taveau's, and Simonart's observations that acetyl-beta-methylcholine possesses practically no 'nicotine' action. They compared the duration of the activity of this drug with that of acetylcholine, as observed by Dale,² and concluded as had Hunt and Taveau that acetyl-beta-methylcholine is more slowly destroyed in the body. Their data show that the effect on the heart rate and blood pressure lasts for about one minute, whereas the effect on the gastro-intestinal tract often persisted for from ten to twenty minutes. Starr, Elsom, Reisinger and

Richards,²⁹ Abbott³⁰ and Starr³¹ have studied the effects of acetyl-beta-methylcholine in normal persons and in patients with a variety of clinical conditions. In normal subjects the subcutaneous administration of 20 mg of the drug was followed by prompt and marked effects. Within a minute after the injection, flushing of the face and neck, generalized sweating, salivation, slight fall in blood pressure, and increase in the pulse rate were observed. The effect on the blood pressure and the increase in the pulse rate passed off within a few minutes. This was usually followed by a pulse rate that was slower than before the injection. The other effects lasted for several minutes. In most of the subjects a transient sinus arrhythmia appeared during the period in which the heart was slowed.

In one subject a typical asthmatic attack occurred immediately following the injection of the drug. The authors consider this the only observed reaction that was at all alarming. Three of the twenty subjects experienced a sense of constriction under the sternum. When the drug was administered by mouth, the symptoms were gradual in onset and mild in character. To produce a significant effect by oral administration, between fifty and a hundred times the subcutaneous dosage was required. Intravenous administration was not attempted.

The effects of intravenous injection of acetylcholine in man were recently studied by Carmichael and Fraser.³² They found that within a few seconds 'after injection the heart rate would slow abruptly and simultaneously the subject experienced a sense of obstructed breathing, causing him to cough, or a feeling of constriction in the chest and other minor sensations, such as burning in the throat. Increased rate and depth of breathing was often noticed. The slowing of the heart, the sensation in the throat, and the desire to cough lasted only a few seconds and were followed by a rise of heart rate to a level greater than before injection, by the appearance of a flush over the face and neck, by a sensation of heat throughout the face, trunk and limbs, and in some subjects by palpitation. This second phase passed off gradually and the whole reaction was over in a half to one minute.' During the phase of slow heart rate the blood pressure fell but returned to the original level or a little higher during the phase of rapid heart rate. The action of the acetylcholine was found to be increased definitely and prolonged slightly by a previous injection of physostigmine, as Hunt³³ had shown in 1917. In one subject, the injection of 30 mg of acetylcholine after a previous administration of physostigmine stopped the heart beating for 118 seconds, and a convulsive attack followed with auricular fibrillation, which lasted two hours.

CLINICAL STUDIES

The effect of acetyl-beta-methylcholine in the treatment of tachycardia was studied by Starr.³¹ Forty-nine attacks of paroxysmal tachycardia were observed. In twenty of these, when pressure over the carotid sinus was the only procedure employed, normal rhythm was reestablished. The other twenty-nine attacks (in nine patients) were treated by the subcutaneous administration of about 30 mg of the drug, and in a few instances carotid pressure in addition was used. Twenty-four attacks in seven patients were promptly terminated. The patients experienced the same symptoms as did the normal subjects, and after a brief cardiac pause, followed by a period of irregularity of both rhythm and intensity of heart sounds and pulse, normal rhythm occurred. Electrocardiographic observations showed a prolongation of the PR interval and an occasional extrasystole. In two cases this was accompanied by blocked auricular beats and a few aberrant ventricular complexes. This momentary disturbance was followed by normal rhythm. The authors ascribe these effects to vagus stimulation. In one patient, who had been receiving digitalis, a complete heart block was momentarily established, followed by a return of the tachycardia. Whether this was due to any summation of the actions of digitalis and acetyl-beta-methylcholine is uncertain.

tain In their experiments on animals, Comroe and Starr were unable to demonstrate such an effect In preventing the occurrence of attacks, quinidine was found to be much more effective

In tachycardia accompanying thyroid disease, and in auricular fibrillation, acetyl beta-methylcholine was without therapeutic effect.

Nahun and Hoff³⁴ recently reported that acetyl-beta-methylcholine prevents the development of ventricular fibrillation in animals suffering from acute benzene poisoning These interesting observations await further confirmation.

Starr studied also the effects of the drug in a variety of conditions involving the blood vessels In Raynaud's disease acetyl-beta methylcholine did not prevent or alleviate the spasm when the extremity was exposed to severe cold, but it appeared to have some beneficial effect in spasm following moderate exposure. Only four cases were studied In four cases of occlusive type of peripheral vascular disease, some relief was noticed in two cases, but it is uncertain whether this can be attributed to the action of the drug Villaret,³⁵ who introduced acetylcholine into medicine by using it in the treatment of various types of peripheral vascular disease, considers its use of therapeutic value Ruiter³⁶ in 1931 reported therapeutic effects following the use of acetylcholine in the treatment of leg ulcers due to circulatory disturbance, and Waters³⁷ has observed similar results However the number of cases they observed was relatively small, and adequate controls are lacking

Whereas Villaret³⁸ believes that the esters of choline which he employed are of some therapeutic value in hypertension Eldahl³⁹ observed no beneficial action of acetylcholine in his twelve patients with hypertension and arteriosclerosis He attributed his failure to the organic changes in the vessels In patients with hypertension, Starr could demonstrate no definite clinical improvements following the use of the drug Moderate doses given subcutaneously cause a momentary fall in the blood pressure, during which period the patients were more uncomfortable than before Oral administration was followed by a decrease in systolic pressure of between 38 to 16 mm of mercury lasting about thirty minutes In some of the patients, the drug exhibited no effect on the blood pressure

The data presented by Starr on the possible clinical improvement in one case each of Cheyne Stokes breathing, one-sided headaches and Meniere's disease are not sufficiently complete to justify an interpretation of the value of the drug in these conditions

The action of acetyl-beta-methylcholine on the gastrointestinal tract has been studied by Abbott⁴⁰ While there was an increase in gastric acidity following the use of the drug in two of the nine normal subjects and in three of the six cases of hypochlorhydria, histamine gave a greater response and caused less systemic reaction than did the acetyl-beta-methylcholine These observations confirm those of Wilkinson⁴¹ who observed that the effect of acetylcholine on the gastric secretion is uncertain and much less pronounced than that of histamine.

In 1921 Le Heux⁴² found that choline increased the peristalsis of the small intestine but that the substance had relatively little effect on the large intestine Arai⁴² a year later reported that with choline he was able to relieve intestinal paresis produced by laparotomy in cats Kuelhewen⁴³ made similar observations in intestinal paresis following prolonged chloroform anesthesia In his normal subjects Abbott found that when acetyl-beta methylcholine was administered subcutaneously while the stomach was empty, the effect was a cessation of the normal hunger contractions When the stomach contained food

the drug increased gastric motility Oral administration of the drug was observed to increase peristalsis of the small intestine, whereas the effect on the colon was much less certain.

Of the fourteen cases of postoperative abdominal distention treated with acetyl-beta-methylcholine Abbott reports nine as exhibiting some symptomatic relief Three cases in which the most favorable results were obtained are reported in some detail While all three patients undoubtedly had severe abdominal distention, only one showed this condition as a complication immediately following operative procedure

COMMENT

Acetyl-beta-methylcholine is a drug of considerable pharmacologic interest. Its actions resemble the "parasympathetic" actions of acetylcholine and appear to produce little or no "nicotine" effect Unlike acetylcholine it is capable of exerting a physiologic effect when administered orally When injected subcutaneously its actions appear to be more prolonged than those of acetylcholine, although the effect on the heart rate and blood pressure persists for only a few minutes, whereas with acetylcholine the effect persists for about a minute. The intravenous injection is likely to prove dangerous (Villaret and Justin-Besançon)⁴⁴

In selected cases of paroxysmal tachycardia not responding to the usual therapeutic measures, the careful administration of graded doses of acetyl-beta-methylcholine is probably of value Overdosage of the drug and administration to patients with asthma should be avoided. For preventing attacks the drug is inferior to quinidine In other forms of tachycardia and in auricular fibrillation, the usefulness of the drug is not apparent.

The clinical data presented are not sufficiently complete to justify an evaluation of the results obtainable in Raynaud's disease. A larger series of such cases should be observed.

In hypertension the value of the drug appears to be limited to the temporary relief of headache. The discomfort experienced by the patients would constitute a contraindication in most cases

The therapeutic value of the drug in intestinal paresis following laparotomy should be more definitely established Unfortunately the evidence presented is insufficient. That the drug increased intestinal peristalsis in normal subjects or in patients with nonsurgical abdominal distention is no indication that the paralyzed intestinal tract of the postoperative patient can be effectively stimulated These effects of the drug should be studied in a larger series of controlled cases

The Council cannot at this time accept acetyl-beta-methylcholine (mecholyd Mecholin) until further evidence is available In the meantime, this preliminary report is issued

The foregoing preliminary report was sent to Merck & Co before publication. The firm replied that it hoped publication and consideration of the name could be deferred. Further consideration of the name is deferred for the present. A few minor revisions have been made in the original preliminary report prior to its publication The Council points out that since the clinical status of the drug is still experimental, a preliminary informative article should be published, that the report is not derogatory to the product but the available evidence is not sufficient to justify its acceptance for general use by the profession at this time. The Council commends Merck & Co for the type of investigation planned or under way, and for its cooperative spirit in dealing with this product The Council will again consider the product and related questions when further evidence is available⁴⁵

BONE MARROW INSUFFICIENCY

The bone marrow is considered today to be an integral organ with many important functions. According to Middleton and Meyer,¹ under normal conditions it is the sole source of the red blood cells, the polymorphonuclear leukocytes and the thrombocytes in adult life. The functioning red bone marrow occupies the entire shafts of the long bones at birth. By the sixteenth year of life, active bone marrow is found in the ends of the long bones, in the flat bones, and in small, spongy bones. The histogenesis of the mature blood cells arising in the marrow is not completely understood. However, it is generally accepted that the root cell or hemoblast is responsible for the development of the polymorphonuclears, the erythrocytes and the platelets. The megakaryocyte of the marrow is believed to be the only source of the thrombocyte, but under disease conditions these large cells may appear in other than myeloid tissue. The delivery of the cellular products of the bone marrow into the circulating blood probably is accomplished by two mechanisms, namely, amoeboid movement of the cells and extrusion by growth pressure. The polymorphonuclear elements and the blood platelets migrate from the marrow into the circulating blood by means of their amoeboid activity, while growth pressure is the potent factor in delivering erythrocytes into the blood stream. There may be separate stimuli to the production of each type of cell derived from the bone marrow, or the energizing force may be a common one for all types of cells. Hemorrhage stimulates the production of blood platelets. Chemotaxis plays an important part in stimulating the production of leukocytes. While there has been a great advance in the knowledge of erythropoiesis made by the well known work of Minot, Murphy, Peabody, Castle, Whipple and others in recent years, the theory of a constant tempo of red blood cell production still appears sound. Bunting holds that a given quantity of bone marrow can produce erythro-

cytes only at a given rate and that for an increased production there must occur an extension of the erythrogenic centers.² Middleton and Meyer say that, so far as is known, lowered oxygen tension is the only normal stimulus to the extension of the bone marrow.

Insufficiency of the bone marrow may result from primary disease of the myeloid system or from a disease that involves this structure secondarily. In either case the result is some form of anemia or other blood dyscrasia. In patients suffering from aplastic anemia there is an absence or extreme paucity of evidence of regeneration of blood cells. There may be little change in the individual erythrocyte. There is usually leukopenia. The platelets are reduced also, and sooner or later purpuric manifestations complicate the picture of anemia. The cases of aplastic anemia reported usually have followed exposure to the toxic action of arsenphenamine, radium, x-rays or benzene. An infection may occasionally lead to total paralysis of the bone marrow. No etiology can be ascribed in some of the cases. The prognosis of idiopathic aplastic anemia is grave, death usually supervening within three months, regardless of the treatment. At necropsy, as would be expected, there is found acellular yellow bone marrow.

Insufficiency of the bone marrow that causes a reduction in the blood platelets may occur from many causes. In cases of essential thrombocytopenia, for example, the most conspicuous feature is the hemorrhagic tendency. According to Minot,³ 60,000 platelets per cubic millimeter is the level below which bleeding occurs. In the purpura haemorrhagica that attends this condition, bleeding occurs in the skin and mucous membrane with epistaxis, hemoptysis, hematemesis, melena and sometimes hematuria. The clotting time is about normal, but the bleeding time is usually prolonged. Simple measures in hemostasis may stop slight attacks of bleeding, again, transfusions will be effective. No one therapeutic agent has been found to be specific. Such measures have been recommended as vitamins A, B and C, viosterol, iron and calcium, ultraviolet therapy, liver therapy, and dietary measures. When the simpler measures fail, roentgen therapy over the spleen or the removal of that organ has been advised. Splenectomy, however, has not been uniformly successful.

Serious bone marrow insufficiency may also manifest itself in the clinical syndrome of agranulocytosis, in which there is a failure of leukopoiesis. Following depletion of the circulating neutrophils there are prostration, fever, and areas of necrosis usually in the mouth, rectum or vagina. The leukocytes alone are affected in most cases, but there may be an extension

1 Middleton W S and Meyer O O Marrow Insufficiency Ann Int Med 8 1575 (June) 1935

2 Bunting C H The Regulation of the Red Blood Cell Supply Contributions to Medical and Biological Research dedicated to Sir William Osler in Honor of His Seventieth Birthday July 12 1919 by His Pupils and Co Workers New York.

3 Minot G R Diminished Blood Platelets and Marrow Insufficiency A Classification and Differential Diagnosis of Purpura Haemorrhagica Aplastic Anemia and Allied Conditions Arch Int Med 101 1062 (June) 1917

of the bone marrow insufficiency producing anemia or a hemorrhagic tendency. The prognosis in agranulocytosis depends largely on the presence of a recognizable cause. Idiopathic neutropenia may undergo remissions, but there is no regularity in their appearance or duration. Middleton and Meyer advise that, by means of appropriate doses of pentnucleotide intramuscularly, every precaution be taken to forestall serious declines in the neutrophils.

Bone marrow insufficiency therefore may manifest itself clinically as aplastic anemia when the marrow fails as a unit, as thrombocytopenia when the blood platelets fail, and as agranulocytosis when there is leukogenic failure.

ACETYL BETA METHYLCHOLINE

For a quarter of a century the cholines have commanded the attention of research workers in medical science. The choline compounds, widely dispersed in nature, have been obtained from many vegetables and organic extracts as well as from certain drugs (especially ergot). The cholines may be considered to be quarternary ammonium bases, they produce two sets of actions: a "muscarine" effect and a "nicotine" effect.¹

As early as 1914, Hunt and Taveau² in an intensive study of cholines reported that one derivative, acetylcholine, was 100,000 times more depressant and only three times more toxic than choline itself. Another derivative in this group that has recently been used in therapeutic trials is acetyl beta methylcholine, described by Taveau² in some of his earlier work. Hunt, at the time he was working in the Hygienic Laboratory of the United States Public Health Service, found that Taveau's preparation differed pharmacodynamically from acetylcholine and the other cholines.² It had the advantage of being effective when given by mouth. It was more slowly destroyed in the body. It possessed a marked "muscarine" effect and practically no "nicotine" effect. The so-called muscarine effect consists of three actions: an inhibitory effect on the heart, a peripheral vasodilatation with an accompanying fall in blood pressure, and a stimulation of gastric and intestinal peristalsis.

The inhibitory effect on the heart led to the use of acetyl methylcholine by Starr³ in paroxysmal tachycardia. The results indicate that carefully graded doses are useful in selected cases not responding to other measures. He found it ineffective in other forms of tachycardia and in auricular fibrillation. The occurrence of a peripheral vasodilatation suggested to Starr that this agent might also prove useful in the spastic types of peripheral vascular disease. His clinical trials point to an effectiveness in these cases and also in cases

of the occlusive type in which there is some degree of spasm. Eldahl⁴ had previously found acetyl methylcholine ineffective in hypertension and arteriosclerosis. He concluded that the presence of organic change in the vessels prevented this action of the drug. Goldsmith⁵ subsequently reported a rise in skin temperature in all types of peripheral vascular disease following the administration of acetyl methylcholine. The stimulation of gastric and intestinal peristalsis has led to its trial by Abbott⁶ in postoperative abdominal paresis.

Elsewhere in this issue of THE JOURNAL is a preliminary report of the Council on Pharmacy and Chemistry (page 281) reviewing the evidence for acetyl beta methylcholine. The Council declares that it is not warranted at present in accepting the product for inclusion in New and Nonofficial Remedies. The character of research developments under the direction of the manufacturers is commended. The Council points out that the evidence for use of the product in abdominal paresis is inadequate, that its use in peripheral vascular disease needs further study, and that it has a limited usefulness in certain types of tachycardia.

Of further interest is the fact that all the "muscarine" effects may be prevented or abolished by atropine. This action of atropine was attributed by Mueller⁷ to a resultant paralysis of the dilator elements. The "nicotine" effect, practically absent in this particular choline, results in a considerable rise in blood pressure. This rise did not usually occur unless the "muscarine" effects had been prevented by previous administration of atropine.

Starr³ described the clinical response to the subcutaneous injection of 20 mg of acetyl beta methylcholine. One minute after injection there was flushing of the face and neck, generalized sweating, salivation, a slight fall in blood pressure, and an increase of pulse rate. The blood pressure and pulse rate returned to normal within several minutes. The other symptoms lasted for a brief interval. In most cases there was a transient sinus arrhythmia.

Additional experimental and clinical evidence may prove acetyl beta methylcholine useful in these clinical conditions. In the meantime, the report of the Council on Pharmacy and Chemistry warns that the present status of this drug does not warrant its recommendation as an established therapeutic measure. The intravenous use of the drug is definitely not recommended. It apparently should not be used in allergic patients. Thorough knowledge of its action and caution are necessary if it is to be used at present. Acetyl beta methylcholine, however, is deserving of further clinical trial by those who have the facilities to conduct controlled therapeutic investigations.

Current Comment

THE EVALUATION OF TESTS FOR SYPHILIS IN STATE AND LOCAL LABORATORIES

During the past year the United States Public Health Service in cooperation with the American Society of Clinical Pathologists and participating serologists published the results of a study undertaken to investigate the relative efficiency of complement fixation and flocculation tests as described by serologists in the United States¹ In determining the relative efficiency of these tests the serologists who originally described the methods were permitted to perform their own tests The conditions under which the specimens were collected and submitted to the serologists have been published² Since the specimens in the original study were examined by the serologists who had described their own methods, or in their laboratories by other specially trained workers, it is possible that the efficiency of the tests may vary considerably when performed by others not so familiar with the details of the procedure The Committee on Evaluation of Serodiagnostic Tests for Syphilis proposes during the next few months to furnish samples of blood to state and local laboratories and possibly to a few private laboratories in order that the efficiency of the serologic work in these laboratories may be studied The conditions under which specimens will be collected and transported will follow those in the original evaluation study The directors of state and local laboratories who desire to participate in the extension of the evaluation of serodiagnostic tests for syphilis are requested to forward an application immediately to the Surgeon General, U S Public Health Service, Washington, D C, in order that careful consideration may be given to all applicants Applications should state the name of the serologic test or tests for syphilis employed in the laboratory, if the test has been modified, the extent of the modification should be specified After all applications have been received, the laboratories will be classified according to the type and modification of serologic tests employed Specimens will then be sent to selected laboratories performing a given test and to the original serologist who described this test About 200 specimens from normal presumably nonsyphilitic individuals and 200 specimens from known syphilitic patients will be collected in sufficient quantity to furnish a comparable sample to all laboratories performing a given test as well as to the serologist who originally described this test A direct comparison between the work of the originator of the test and the work of the technicians in the laboratories performing his test will therefore be possible From time to time the committee will publish the results of this extended evaluation work, showing the reports of the serologist who originated a test compared with the

reports by the laboratories employing his technique The method followed by the committee in evaluating serodiagnostic tests for syphilis has been endorsed by the American Dermatological Association The Conference of State and Territorial Health Officers with the United States Public Health Service also passed a resolution during its 1935 meeting approving the method and its extension to include the work in state and local laboratories

EXPERIMENTAL HYPERTENSION

The introduction of an effective method for the production of experimental hypertension by Goldblatt and his associates¹ has opened a new field in research Until recently, no method had been available to produce in animals a persistent rise in blood pressure comparable to that which occurs in human beings By means of an ingenious silver clamp applied to the renal arteries, Goldblatt induced lasting renal ischemia in dogs with resultant increases in systolic blood pressure to from 200 to 240 mm of mercury, in occasional animals the arterial pressure approached 300 mm The hypertension lasted indefinitely, often with no detectable change beyond normal limits either in renal function or in the concentrations of urea, total nonprotein nitrogen, creatinine or guanidine in the blood The condition produced by this means in animals resembles closely that associated with so-called benign nephrosclerosis or so-called malignant nephrosclerosis in man, depending on whether the renal ischemia is moderate or severe The suggestion has been made that the arterial hypertension associated with disease of the kidney in man may be due to impulses conducted from the kidneys by way of the extrinsic renal nerves to the vasomotor center Page² of the Rockefeller Institute, employing the method of Goldblatt, undertook to test this theory experimentally He confirmed in detail and extended the observations reported by the latter investigator and his collaborators, he found further that severing the extrinsic renal nerves was without detectable effect on the hypertension induced by renal ischemia A second method also was employed by Page This consisted in explanting the kidneys to a position under the skin of the back, after the wound had healed, the kidneys were exposed to roentgen radiation The rise in blood pressure induced by this means was less severe and of shorter duration than that induced by applying a clamp to the renal artery With this method also, renal denervation had no effect on the resultant hypertension Page concludes, "Since the production of arterial hypertension in dogs by constricting the renal arteries, or by irradiation of the kidney with x-ray, is not affected by preliminary stripping of the renal pedicle of its extrinsic nerve supply, these nerves do not appear to participate in the genesis of renal hypertension" Measurements of blood urea nitrogen, plasma protein, total fat, total cholesterol,

lipid amino nitrogen, total lipid nitrogen and phosphatide showed no significant changes following production of renal ischemia by arterial constriction, a slight rise in blood hemoglobin occurred. The solution of various problems in cardiovascular and renal disease has been advanced by means of these new methods of research.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ALABAMA

Graduate Courses in Pediatrics—The Alabama State Medical Association is sponsoring a series of graduate lectures in pediatrics, the first of which will be given some time this summer in cooperation with the Children's Bureau, U. S. Department of Labor. The course will be patterned along the lines of courses in obstetrics which have been conducted in recent years by Dr. James R. McCord, Atlanta, in various states. Dr. T. Cook Smith, assistant professor of pediatrics, University of Louisville School of Medicine, Louisville, Ky., and Dr. John M. Saunders, instructor in pediatrics, Vanderbilt University School of Medicine, Nashville, Tenn., will direct the course, with others assisting.

CALIFORNIA

Plague Infected Ground Squirrel—A plague infected ground squirrel was shot on a ranch in Lassen County, near Adin, according to the director of the state department of public health, June 24.

Personal—Dr. Alfred C. Reed, director of the Pacific Institute of Tropical Medicine, University of California, received the doctorate of science at the annual commencement of Pomona College, where he gave an address on "Environmental Medicine."—Dr. Mary B. Ritter, Berkeley, received the honorary degree of doctor of laws recently from the University of California.

ILLINOIS

Hospital News—A new \$100,000 building at the Elgin State Hospital for the Insane collapsed, July 3, injuring seven people. Steel trusses that were being set in the foundation gave way, it was stated.

Committee on Infantile Paralysis—The appointment of a committee on infantile paralysis is announced by the Illinois State Department of Health, to coordinate all control activities incident to an outbreak of the disease. With Howard J. Shaughnessy, Ph.D., Springfield, the following physicians make up the committee:

Sidney O. Levinson, Chicago
Philip Lewin, Chicago
Paul H. Harmon, Chicago
George W. Staben, Springfield
Winston H. Tucker, Springfield
Lloyd L. Arnold, Chicago
Frank Garm Norbury, Jacksonville
Frank J. Jirka, director of the state department of health.

Chicago

Annual Golf Tournament—The Chicago Medical Society will hold its annual golf tournament at the Medinah Country Club, August 7. Those eligible to play are the officers, trustees and past presidents of the society, and members of the council and officers of the branch societies. The trophy is a cup named in honor of the late Dr. J. Warren Van der Slice and donated by Dr. Herman L. Kretschmer in 1933. These tournaments were inaugurated in 1932 by Dr. Austin A. Hayden.

Dr. Hudson Goes to Ohio State—The appointment of Dr. Noel Paul Hudson since 1930 professor of bacteriology, University of Chicago, as professor and chairman of the department of bacteriology at Ohio State University School of Medicine, Columbus is announced. He succeeds Dr. Charles B. Morrey, who has resigned. Dr. Hudson took with him as assistant professors in the department Floyd S. Markham, Ph.D., Jergen M. Birkeland, Ph.D., and Dr. Oram C. Woolpert, all graduates of the University of Chicago. Dr. Hudson graduated from Harvard Medical School in 1925.

IOWA

Death from Rocky Mountain Spotted Fever—The death of a child, 8 years of age, at Marion, Linn County, June 11, as the result of Rocky Mountain spotted fever, following nine days of illness, is reported in the *Journal of the Iowa State Medical Society*. It is the first case of the disease reported in the state in 1935. A tick was found in the child's scalp, May 31, several days before onset of symptoms, after she had been playing in her front yard.

Society News—At a meeting of the Davis County Medical Society in Bloomfield, June 25, Drs. Glenn C. Blome and Harold H. Webb, Ottumwa, discussed fractures.—Dr. Everett D. Plass, Iowa City, addressed a joint meeting of the Dickinson and Emmet County medical societies, June 27, in Spirit Lake, on "Diagnosis and Treatment of Leukorrhea."—At a meeting of the Johnson County Medical Society in Iowa City, June 5, Dr. Samuel S. Steinberg spoke on "The Beneficial Effect of High Sodium Chloride Intake in the Treatment of Irradiation Sickness" and Dr. Ernst Freund, "Hypertrophic Arthritis of the Hip."—An illustrated lecture on "Gonorrhea in the Female" was presented before the Washington County Medical Society, June 25, by Dr. William F. Mengert, Iowa City.—Dr. Charles Corbin Yancey, Sioux City, addressed the Sioux County Medical Society, June 20, on "Early Diagnosis of the Adult and Childhood Types of Tuberculosis."

KANSAS

Court Upholds Revocation of Brinkley's License—The revocation of the license to practice medicine of Dr. John R. Brinkley by the Kansas Board of Medical Registration and Examination was upheld in an order, June 14, issued by U. S. District Judge Tilman D. Johnson, Salt Lake City. Contending that he had been deprived of property without due process of law, Brinkley sought in his action to enjoin the state board from enforcing its order revoking his certificate. The ruling of the judge was a complete endorsement of the board's action in revoking Brinkley's license in 1930. In answering Brinkley's attorneys the judge said, according to the bulletin of the Sedgwick County Medical Society:

I think that under the general terms of the statute the board is empowered to protect the public against conduct which is clearly against public interest and therefore necessarily unprofessional the same as if the legislature had specifically denounced and prohibited such practice. Dr. Brinkley's methods were so notorious that ignorance of them by members of the board was an impossibility.

It is, I think, perfectly clear from these quotations [from the testimony before the medical board at its hearing] that Brinkley made the practice of medicine a business adopting usual present-day methods of propaganda by use of mail and radio.

These methods are not only in conflict with ethics of the profession but are in my opinion in conflict with the best interests of the public and irrespective of the value of the operations performed by him at the hospital or the benefits to individuals using prescriptions given through radio broadcasting the possibilities of injury to the general public resulting from such methods are so apparent that if such methods became general its mere statement is sufficient.

MARYLAND

Tularemia in Baltimore from Tick Bite—A case of tularemia transmitted by a tick bite was reported in Baltimore early in June. It is the first instance of insect transmission of tularemia to be reported in the state, according to the state department of health, proving that the infection may result not only from handling infected wild rabbits but also from the bites of infected Maryland wood ticks. The patient had not been in contact with rabbits for several months prior to his illness. After he had removed a wood tick that had been engorging for two or three days, an ulcer developed at the site of the tick bite. The patient's lymph glands enlarged he had fever, headache and muscular pains. Laboratory tests confirmed the diagnosis of tularemia.

MICHIGAN

Memorial to Dr. Warthin—A bronze plaque of the late Dr. Aldred S. Warthin was presented to the University of Michigan School of Medicine, Ann Arbor, June 15 by persons who had been in the department of pathology when he was director. The memorial hangs in the West Medical Building. Dr. Warthin was associated with the university from his graduation there in 1891 until his death in 1931, since 1903 he had been professor of pathology and director of the pathologic laboratory.

Dr. Parker Honored—The honorary degree of doctor of science was conferred on Dr. Walter Robert Parker by the University of Michigan at its recent commencement. For twenty-eight years Dr. Parker was professor of ophthalmology at the university, since 1933 he has been professor emeritus.

In 1915 he was chairman of the Section on Ophthalmology of the American Medical Association and, in 1916, he was awarded the Knapp Medal by that section for his research on "The Relation of Tension of Eyeball to Papilledema"

MINNESOTA

State Medical Meeting and Election—Dr William W Will, Bertha, was elected president of the Minnesota State Medical Association at the annual meeting in Minneapolis, June 24-26. He will take office January 1, succeeding Dr William A Coventry, Duluth. Drs Eugene G McKeown, Pipestone, and Carl W Rumpf, Faribault, were chosen vice presidents, and Drs Edward A Meyerding, St Paul, and William H Condit, Minneapolis, were reelected secretary and treasurer, respectively. The next annual meeting will be held in Rochester. The society held joint sessions with the American Association for the Advancement of Science, which was holding its annual meeting in Minneapolis. Guest speakers at the state medical meeting included the following physicians:

Harry L Alexander, St. Louis: Present Status of Clinical Allergy.
Frank H Lahey, Boston: Newer Developments in Hyperthyroidism and Hyperparathyroidism.
Edmund Andrews, Chicago: Pathogenesis of Gallbladder Disease.
Theodore L Sawyer, Milwaukee: Symposium on Diseases of the Blood: Role of Drug Allergy in the Etiology of Primary Granulocytopenia.
Walter A Bloodorn, Washington, D. C.: Role of Iron in the Treatment of Anemia.
William F Murphy, Boston: What We Have Learned About Pernicious Anemia During Ten Years of Treatment with Liver.
Louis W Sauer, Evanston, Ill.: Prevention of Whooping Cough with Bacillus Pertussis Vaccine.
Elmer L Sevringhaus, Madison, Wis.: Endocrine Therapy.
Everett D Plass, Iowa City: Simplification of Obstetric Care.
John F Birnhill, Miami Beach, Fla.: Suppurations of the Neck: Cause, Diagnosis and Treatment.
William S Middleton, Madison, Wis.: Prognosis and Treatment of Coronary Occlusion.
Thomas G Orr, Kansas City, Mo.: Venoclysis—A Consideration of Its Possible Dangers.

Dr Murphy addressed a joint meeting of the society with the association for the advancement of science, Monday evening, June 24, on "Diseases of the Blood," and Dr Percy Brown, Egypt, Mass., delivered the Russell D Carman Memorial Lecture at an afternoon session, Tuesday, on "The Inception and Development of Fluoroscopy: The Influence of Carman on Its Status in America."

MISSOURI

Dr Muckenfuss Receives New York Appointment—Dr Ralph S Muckenfuss, assistant professor of medicine, Washington University School of Medicine, St. Louis, has been appointed temporary assistant director of the bureau of laboratories of the New York City Department of Health. Within a few months the New York Times stated, a civil service examination will be held to select a permanent appointee for the position who will be assistant and later successor to Dr William H Park, the present director, who will retire on account of the age limit. Dr Muckenfuss graduated from Emory University School of Medicine, Atlanta, and served for a time on the staff of the Rockefeller Institute for Medical Research, New York.

NEW YORK

Physicians Appointed to Industrial Council—Governor Lehman has appointed the following physicians to the state industrial council: Drs William D Johnson, Batavia; Edward C Podvin, Horace E Ayers, New York; and William Linder, Brooklyn. They will represent physicians in their relation to the department of labor in matters concerning the new workmen's compensation law passed by the last legislature. Albert W Bailey, D. O., Schenectady, was also appointed.

Heads Letchworth Village Twenty-Five Years—Dr Charles S Little, superintendent of Letchworth Village, Thells, recently celebrated his twenty-fifth year of service at the state institution. Dr Little went to the colony in 1910 and lived in a tent while the first buildings were being erected. It was said: "There are now eleven buildings and two more will be required to finish the building program, which will provide adequate care for 3,650 patients, at a cost of \$10,000,000."

New York City

United Hospital Fund to Seek Nine Millions—A campaign for \$9,440,000 will be launched in the fall by the United Hospital Fund, it was announced at a luncheon June 25. Mr David H McAlpin Pyle, president of the fund, estimated that this amount would be needed by the fifty-two voluntary hospitals participating in the fund, to stop pyramiding of deficits. Notwithstanding inroads on capital, the hospitals had unpaid bills amounting to \$5,700,000 in addition to mortgage and long term liabilities of \$14,000,000.

Hearing Tests on School Children—According to a report of the Emergency Relief Bureau, tests of the hearing of 606,546 school children, made as a special project of the bureau, showed that about 10 per cent had a hearing loss in one ear or both. Of the total number, 4,000 were found to be seriously afflicted and are receiving lip-reading instruction from seventy-nine teachers, who would otherwise be unemployed. The workers were trained in the use of the audiometer at the New York League for the Hard of Hearing, and all children were examined by physicians, who prescribed treatment. Parents who were unable to afford the services of a physician were advised to take their children to clinics, it was said.

Dr Park to Receive Roosevelt Medal—Dr William Hallock Park, director of the bureau of laboratories of the New York City Department of Health, will receive the Roosevelt Medal for 1935, it was announced July 12 by the Roosevelt Memorial Association. The medal will be presented at a banquet at Roosevelt House October 27, the seventy-seventh anniversary of the birth of Theodore Roosevelt. The citation refers to Dr Park's "distinguished service in the administration of public office." Dr Park has been director of the health department laboratories since the bureau was established in 1894 and is professor of bacteriology and hygiene at New York University College of Medicine. In recent years he has received the Public Welfare Medal of the National Academy of Sciences and the Sedgwick Medal of the American Public Health Association, of which he was president in 1923. The Roosevelt awards were established in 1923 and are given annually in some field associated with Mr Roosevelt's career.

OHIO

Dr Thompson Honored on Hundredth Birthday—The town of Bethel, under the leadership of the local chapter of the Independent Order of Odd Fellows, held a community celebration July 6, in honor of the one hundredth birthday of Dr William Eberle Thompson. At a public reception Dr John A Caldwell, Cincinnati, president of the Ohio State Medical Association, paid tribute to Dr Thompson's long career and an oil painting of him was unveiled. Dr Thompson was born in Bethel of a family in which there have been twelve physicians including his father. He graduated from the old Cincinnati College of Medicine and Surgery in 1860. During the Civil War Dr Thompson was assigned as surgeon in the Seventh Ohio Infantry. He has had an office throughout all these years on the same street and still conducts a limited practice.

OKLAHOMA

Society News—Speakers at the quarterly meeting of the Southern Oklahoma Medical Association at Sulphur, June 4, included Drs Richard M Burke, Sulphur, on "Differential Diagnosis of Tuberculosis and Nontuberculous Chest Diseases"; John B Morey, Ada, Purpura Haemorrhagica; and Anson L Clark, Oklahoma City, Fever Therapy—Its Possibilities and Limitations. At a meeting of the Southeastern Oklahoma Medical Association in Durant, June 27, speakers included Drs Benjamin B Kies, McAlester, on "Lymphoid Tissue"; Charles R Huckabay, Idabel, "Management of Genito Urinary Diseases by the General Practitioner"; and Rufus H Sherrill, Broken Bow, Common Complications in Obstetrics. Dr William H Bailey, Oklahoma City, among others, addressed the Woodward County Medical Society at Supply, June 11, on early diagnosis of malignant tumors.

PENNSYLVANIA

Law Enforcement Activities—The state bureau of enforcement has prosecuted the following persons among others, in the past few months, for illegal practice of the healing art:
Ashton Will Somerset fined \$100 and costs with six months imprisonment.
R D Singh, Mechanicsburg, \$50 and costs with sixty days in jail.
A R Daley, Sharon, fined \$100 with six months imprisonment.
Theodore R Anderson, Philadelphia, one to five years imprisonment.
Eugene Harsch, Pittsburgh, fined \$100 and costs.

Philadelphia

Faculty Changes at Jefferson—During the past session the following promotions and appointments have been made in the faculty of Jefferson Medical College:

Dr Warren B Davis, clinical professor of surgery.
Dr Edward F Corson, associate professor of dermatology.
Dr Benjamin P Weiss, associate professor of neurology.
Drs Clifford B Lull, Harry Stuckert and Thaddeus L Montgomery, assistant professors of obstetrics.
Dr John T Farrell, Jr., assistant professor of roentgenology.
Dr Henry B Decker, assistant professor of dermatology.

TENNESSEE

Personal—Dr John W L Cooper has been appointed health officer of Chattanooga, to succeed Dr Frederick C McIsaac.

Hospital Superintendents Appointed—Dr Eugene B Elder, superintendent of Knoxville General Hospital for about seven years, has been appointed superintendent of Erlanger Hospital, Chattanooga. Dr Andrew Smith, chief of staff at the Knoxville hospital for the past three years, has been appointed to succeed Dr Elder as superintendent.

Faculty Changes at Vanderbilt—The following promotions in the faculty of Vanderbilt University School of Medicine, Nashville, were announced recently, to be effective July 1.

Drs William R Cate Robert C Derivaux and Hollis E Johnson to be associate professors of clinical medicine.

Drs William Bush Anderson and Milton S Lewis associate professors of clinical obstetrics.

Dr Benjamin H Robbins associate professor of pharmacology.

Dr John M Lee associate professor of clinical pediatrics.

Dr Henry Carroll Smith associate professor of clinical ophthalmology.

Dr Edward H Barkadale associate professor of urology.

Dr John S Cayce assistant professor of clinical obstetrics.

W Ray Bryan Ph.D assistant professor of physiology.

Dr Henry L Douglass assistant professor of clinical urology.

VIRGINIA

Dr Broders Appointed Professor—Dr Albert C Broders, Rochester, Minn., has been appointed professor of surgical pathology and director of cancer research at the Medical College of Virginia, Richmond. Dr Broders is a native of Virginia and a graduate of the Medical College of Virginia. He has been on the staff of the Mayo Clinic for several years.

Society News—The Warwick County Medical Society held a joint meeting with the Peninsula Dental Society at the James River Country Club May 14, with Dr Fletcher D Woodward, University, as speaker on 'The Management of Recent Fractures of the Nose'.—A discussion of state medicine, social medicine and compulsory sickness insurance featured a meeting of the Clinch Valley Medical Society at the Lonesome Pine Country Club near Norton, May 24, speakers were Drs Francis H Smith Abingdon president of the Medical Society of Virginia, Alex F Robertson Jr, Staunton and Irl C Riggan, Richmond, state health officer.

Medical College News—A portrait of the late Dr George Paul La Roque, professor and head of the department of clinical surgery at the Medical College of Virginia, Richmond, was presented to the college May 28 by Omega Upsilon Phi and Phi Beta Pi. Dr William Lowndes Peple made the presentation address and President William T Sanger accepted the portrait, which will be hung in the college library. Gov George C Peery made the principal address at the annual commencement, May 28, at which seventy-six physicians were graduated. Dr Karl S Blackwell, Richmond was elected president of the alumni association.—The medical graduates of 1925 presented to the University of Virginia Department of Medicine at the annual commencement activities, June 8 a portrait of the late Dr John Staige Davis, professor of medicine from 1900 to 1930. Dr David R Lyman, Wallingford, Conn. of the class of 1899, gave the commencement address, June 11, when fifty-four medical graduates received diplomas.

WASHINGTON

State Medical Meeting at Everett—The forty-sixth annual meeting of the Washington State Medical Association will be held in Everett, August 12-14. A tentative program lists the following guest speakers:

Dr Olin West Chicago Secretary American Medical Association
Dr Edward B Shaw San Francisco Acute Anterior Poliomyelitis
Dr Albert H Rowe, San Francisco Food Allergy
Dr Charles Ulysses Moore Portland, Ore. Studies in Rickets. Report of 1,000 Cases
Dr Herbert W Riggs Vancouver B C Pain Its Relation to Diagnosis

The program also announces the following addresses by Washington physicians:

Dr James F Scott Yakima Extraperitoneal Cesarean Section
Dr Kenneth A Sherwood Kirkland Prognosis in Chronic Arthritis
Dr Arnold W Hackfield Seattle Influence of Modern Psychiatry on Medical Thought
Dr Henry H Skinner, Yakima Abruptio Placentae
Dr Arthur C Crookall Seattle Internal Hemorrhoids Determination of Method of Treatment
Dr Charles E Hagyard Seattle Acute Pancreatic Neurosis
Dr Frank J Clancy Seattle What About State Medicine?
Dr Walter W Ebeling Burlington, Rate of Absorption of Various Fluids by the Bowels

The Washington State Medical Golf Association tournament will be held Monday August 12 at the Everett Golf and Country Club followed by the golfers annual dinner.

WISCONSIN

Personal—Dr William C Felton was recently appointed health officer of Appleton to succeed Dr Frank P Dohearty.—Dr Amy Louise Hunter, New Haven, Conn., has been appointed supervisor of the state bureau of maternity and child welfare to succeed Dr Charlotte J Calvert, who recently retired. Dr Hunter graduated from Yale University School of Medicine in 1930 and received the degree of doctor of public health at Yale in 1934.

State Society to Collect Historical Material—Pertinent papers, books and instruments bearing on the history of medicine in Wisconsin are to be collected by the State Medical Society of Wisconsin to form a museum and it is expected that after several years a history of medicine in the state may be written. The State Historical Society has agreed to act as custodian of the material. The *Wisconsin Medical Journal* asks the interest and assistance of physicians in assembling relics and mementos and in preparing articles on individual physicians, institutions, medical practices and the like for publication.

Society News—Dr George W Crile Cleveland addressed the Green Bay Academy of Medicine at its annual meeting, recently, on 'Surgical Treatment of Polyglandular Disease, Hypertension and Epilepsy'.—At a meeting of the Sixth District Medical Society in Oshkosh, June 7 speakers were Drs Philip W Brown and Claude F Dixon, Rochester, Minn., on 'Medical and Surgical Treatment of Rectal Carcinoma' and Oscar Lotz, John O Dieterle and Samuel G Higgins, all of Milwaukee on "Diagnosis of Early Tuberculosis," 'Use of Kirschner Wire in Maintaining Reduction of Joint Fractures' and "Surgical Care of Eye Injuries," respectively.

Test of Birth Registration—The bureau of vital statistics of the state board of health recently completed a test on the accuracy of birth registration in all cities in the state with a population of 20,000 or more. It was found that in sixteen cities samples ranging from 11.6 to 25 per cent of the total number of births reported over a period of thirteen years showed 98 per cent completeness of registration. Janesville had 100 per cent registration in 15.3 per cent of all births. The lowest percentage found was 96.8 in Green Bay. In the survey letters were sent to nearly 50,000 couples whose names were taken from the marriage records in each city. Only couples in which the bridegroom was 30 years old or younger and the bride 25 or younger were considered and only first marriages for both were included. Births reported by the parents were checked against certificates in the state board's files. It was found that the accuracy of registration has increased from 94.6 in 1921 to 98.6 in 1933. Practically all births in Wisconsin are attended by physicians. The percentage increased in the thirteen years from 90.7 to 97.2 per cent, the study showed.

GENERAL

Society News—The American Dietetic Association will hold its annual meeting in Cleveland, October 28-31. Among speakers will be Drs Morris Fishbein Chicago Editor of *THE JOURNAL*, on 'Food Fads and Fallacies,' and Wingate Todd, Cleveland, "Food for Fitness".—The American Psychiatric Association announces removal of its offices to the New York Academy of Medicine 2 East One Hundred and Third Street New York.

Association for Study of Goiter—Dr Nelson M Percy, Chicago, was chosen president-elect of the American Association for the Study of Goiter at the annual meeting in Salt Lake City June 24-26, Dr Julius R Yung, Terre Haute, Ind. was installed as president. Among speakers were:

Dr Robertson Ward San Francisco Malignant Goiter—Statistical Survey of Sixty Cases with Comparison of Geographical Types
Dr Russell M Wilder Rochester Minn. The Etiology of Hyperparathyroidism
Dr George W Swift Seattle Wash. Malignant Exophthalmos
Dr Frederick A Collier Ann Arbor Mich. Riedel's Struma
Dr Willard O Thompson, Chicago Quantitative Observations on the Effect of Iodine in Exophthalmic Goiter in Chicago
Dr Arnold Minning Denver Tendency Toward Medical Treatment of Exophthalmic Goiter

Dr Wilder addressed a public meeting Monday evening June 24 on 'Prevention and Cure of Goiter'. It was voted to hold the next session in Chicago.

Pacific Northwest Medical Meeting—The fourteenth annual meeting of the Pacific Northwest Medical Association was held in Spokane Wash., June 27-29. Lecturers were Drs Fred W Rankin, Lexington, Ky., who discussed, among other topics cancer of the breast and of the rectum and selection of gastric and duodenal lesions for surgery. Loyal Davis, Chicago neurologic surgery. James Edwin Wood Jr, University, Va., rheumatic fever cardiac edema, pregnancy and hyper-

tension, Tracy B Mallory, Boston, pathology of asthmatic paroxysms, hyperparathyroidism and pathogenesis of peptic ulcers, Arno B Luckhardt, Chicago, physiology of the hypophysis and analgesic drugs, and George E Brown, Rochester, Minn, diseases of the circulation and of the sympathetic nervous system. Dr Russell T Congdon, Wenatchee, Wash, was chosen president-elect, Drs Banner R Brooke, Portland, Ore, and George O A Kellogg, Nampa, Idaho, vice presidents, and Clyde W Countryman, Spokane, secretary. Dr Charles T Sweeney, Medford, Ore, was installed as president. The 1936 meeting will be in Portland.

First Tuberculosis Cottage Rededicated—In a rededication ceremony during the annual meeting of the National Tuberculosis Association in Saranac Lake N Y, June 25, a bronze plaque was placed on "Little Red," the first cottage in America for open air treatment of tuberculosis, erected by Dr Edward Livingston Trudeau in 1884 in Saranac Lake. The plaque was designed and executed by Mr A di Bona, a patient at Trudeau Sanatorium "Little Red," which is now used as a museum, was recently moved to a new location on the main entrance road to the sanatorium. Using a picture of the cottage on the 1934 Christmas seal, the National Tuberculosis Association commemorated the fiftieth anniversary of the building of the cottage which was the nucleus of the Trudeau Sanatorium. Dr Trudeau was the founder and first president of the association. On the eighty-sixth anniversary of his birth, Oct 5, 1934, officials of the New York state committee on tuberculosis and public health presented to the sanatorium a picture of the cottage in a ceremony attended by physicians from all parts of the state.

Birth and Infant Mortality Rates Rose in 1934—The Bureau of the Census announces in its annual summary of statistics on live births, infant mortality and stillbirths in the United States that the birth rate in 1934 was 17.1 per thousand of estimated population as compared with 16.6 in 1933. The infant mortality rate for 1934 was 59.9 per thousand live births, as compared with 58.1 in 1933. The stillbirth rate was slightly lower, 3.6 as compared with 3.7 in 1933. New Mexico had the highest birth rate (27.9) as well as the highest infant mortality rate (132.1). States with the next highest birth rates were North Carolina and Utah, each 24.1, South Carolina, 24, Alabama, 23.4, West Virginia, 23.2, and Mississippi, 23. The lowest rates were in California, 12.7, and New Jersey, 12.9. The highest infant mortality rates after New Mexico were Arizona, 103, South Carolina, 86.1, Georgia, 78.9, and North Carolina, 77.4. The report points out that the two Western states have large numbers of nomadic Mexicans and Indians and the Southern states large Negro populations. The lowest death rates were those for Oregon, 39.8, and Washington, 43. Mortality rates in several large cities were New York, 52.1, Chicago, 47.7, Los Angeles 53.2, Detroit, 50.4, Boston, 57.5, Baltimore, 64.9, New Orleans, 81.5, and Seattle, 41.3. All these rates represent decreases from the figures of 1933 except the last three.

Medical Bills in Congress—Change in Status H R. 8554, the Second Deficiency Appropriation Bill, has been reported to the Senate, with amendments (S Rept. No 1085). As passed by the House, this bill proposed an appropriation of \$20,000,000 to provide additional hospital and domiciliary facilities for veterans. To this sum the Senate Committee on Appropriations added \$2,000,000 "to be expended for hospital and domiciliary facilities, subject to the approval of the Federal Board of Hospitalization and the President at the following existing facilities: Newington, Conn., Fort Lyon, Colo., North Little Rock, Ark., and Johnson City, Tenn." **Bills Introduced** S 3276, introduced (by request) by Senator La Follette, Wisconsin, propose to pay compensation of not less than \$10 monthly to any person totally blind who is or may hereafter become entitled to hospital or domiciliary care under veterans' regulations and, further, to permit such persons to elect to receive monthly the monetary value of hospital care, in lieu thereof. S 3271, introduced by Senator George, Georgia, proposes, for the purposes of income tax, to permit corporations to deduct charitable and other contributions. H J Res 354, introduced by Representative Wallgren, Washington, proposes to establish a commission to formulate a national policy relative to benefits for veterans and their dependents. H R 8849, introduced by Delegate Dimond, Alaska, proposes to construct a hospital for the insane of Alaska. H R 8874, introduced (by request) by Representative McSwain, South Carolina, proposes that for the purposes of promotion there shall be credited to officers of the Medical Corps all active service as officers of the Medical Reserve Corps rendered by them between April 23, 1908, and April 6, 1917.

Changes of Status of Licensure—At a meeting of the Florida State Board of Medical Examiners in Jacksonville, June 17, the following action was taken:

Dr Albert J Coleman, Cotuit, license restored.

The New York State Board of Medical Examiners reports the following action:

License of Dr Julius Phillips, Brooklyn, revoked April 26 following his conviction on a charge of manslaughter by an illegal operation.

The Public Health Council of West Virginia reports the following revocation of licenses, dated March 19:

Dr William J Porter, Charleston, and Dr Clavius Clyde Coffindaffer, Shinnston, for violation of the Harrison Narcotic Law, both are serving sentences in the federal prison at Leavenworth, Kan.

The Texas State Board of Medical Examiners has reported the following action taken at a meeting in June:

Dr Gustav Raphael Gerson, Houston, license restored provided he does not apply for a narcotic permit or use narcotics within the next five years.

The Massachusetts Board of Medical Registration recently announced the following action:

Dr Rafael Reyes Garcia, formerly of Springfield, license restored June 20.

At a meeting of the Arizona State Board of Medical Examiners in April, the following action was taken:

Dr Richard McClellan Francis, Flagstaff, license revoked following his conviction of a narcotic charge.

Typhoid Epidemic in a Circus—Final Report—The U S Public Health Service has recently published a final report of its investigations of the epidemic of typhoid that occurred in the Ringling Brothers and Barnum and Bailey Circus in the summer of 1934 (THE JOURNAL, Aug 4, 1934, p 350). The disease was first recognized in Detroit, where sixty-eight employees were hospitalized July 23 and 24 with symptoms of typhoid. The circus physician asked the help of the Detroit and Michigan state departments of health and because of the interstate operations of the circus the federal health service was invited to participate in the investigation. Nine persons were sent back to Detroit July 25 from Flint, making seventy-seven hospitalized in Detroit, forty-four of whom proved to have typhoid. As the circus proceeded on its schedule, 141 persons were left in hospitals in various cities, seventy-four of them proved to have typhoid. Exhaustive investigation of the personnel for carriers, and of the food and ice supply gave no significant information. Bathing in polluted waters was ruled out. An outbreak of diarrheal enteritis affecting almost the entire personnel occurred July 7, 9, when the circus was in western Pennsylvania. Many of those who had typhoid dated their illness back to this outbreak. The typhoid epidemic began about fourteen days after this, the usual incubation period. The distribution among the circus personnel was more or less uniform, all groups being affected except trammens, porters and elephant men, whose water supply was separate from that of the rest of the circus. Water for the general use of the circus is obtained from city water supplies on contract and it was therefore difficult to account for the fact that the circus personnel became infected while local communities were free from typhoid. Sanitary practices within the circus were found to be extremely crude. Water was usually served in a barrel, keg or bucket equipped with a common dipper or cup. Sewage and garbage disposal were far from efficient, and practically no precautions were taken against flies. Dishwashing was inefficiently done in lukewarm water with insensitizing dish towels. Food handlers had not been examined for communicable disease, and their personal cleanliness was far below standard. No effort had been made to require or encourage typhoid inoculations. On recommendation of the health officials, sanitary measures to remedy these conditions were instituted and a physician and a sanitary officer were added to the personnel for the rest of the season to supervise the changes. For future guidance of the circus regimen a set of standard sanitary regulations was drawn up by the federal investigators. The regulations were published in *Public Health Reports*, June 7, 1935, page 797.

LATIN AMERICA

Congress of Physical Therapy—The first annual meeting of the Latin America Congress of Physical Therapy, X Ray and Radium will be held in Mexico City August 29-September 5, with the National University of Mexico as host. Delegates to the congress wishing to present papers will submit the titles of their papers together with an abstract to Dr Madge C. L. McGuinness, 1211 Madison Avenue, New York, or Dr Cassius Lopez de Victoria, 1013 Lexington Avenue, New York. The program will be divided into sections representing medicine and

surgery, fractures in their various specialties, electrosurgery, fever therapy, short and ultra-short wave therapy, light therapy, massage, radium and x-ray therapy and exercise. A special nineteen day convention cruise has been arranged with steamer, rail, hotel and sightseeing costs included in one all-expense fee, under the direction of the American Express Company

Government Services

Positions Open in Children's Bureau

The U S Civil Service Commission announces open competitive examinations for several positions in the Children's Bureau, Department of Labor. Applicants must have graduated from a recognized medical school and must have served one year of internship, in addition, certain experience is required. Optional subjects are pediatrics, obstetrics, orthopedics and general practice (maternal and child health). Entrance salaries range from \$2,600 to \$5,600 a year, less a deduction of 35 per cent toward a retirement annuity. Full information may be obtained from the secretary of the U S Civil Service Board of Examiners at the postoffice or customhouse in any city which has a postoffice of the first or second class or from the commission at Washington, D C

Positions Open for Statisticians

The U S Civil Service Commission announces competitive examinations for six positions with the Bureau of the Census, Department of Commerce, two of which are in the division of vital statistics principal statistician and senior statistician. Applicants for these two positions must have been graduated from medical schools of recognized standing and must have had thorough training in statistics and also in public health, psychiatry or psychology. They must not have reached their fifty-third birthday and must be in sound physical health. Forms for applications, which must be filed not later than July 29 with the Civil Service Commission at Washington, D C, may be obtained from the commission, from any first class postoffice or from the commission's district offices in Atlanta, Boston, Chicago, Cincinnati, Denver, New Orleans, New York, Philadelphia, Seattle, St. Louis, St. Paul, San Francisco, Honolulu, San Juan P R, and Balboa Heights, C Z. The exact title of the examination desired should be stated in the application form.

Wellcome Prize Competition

The Wellcome Prize for 1935 a gold medal including a cash prize of \$500, will be awarded for the research most valuable for the military service performed in any branch of medicine, surgery or sanitation. *Military Surgeon* announces. Reports of not more than 10,000 words (tabular matter excepted) must be forwarded to the Secretary Association of Military Surgeons of the United States, Army Medical Museum, Washington, D C so as to arrive not later than August 15. Five copies should be sent, signed by a nom de plume or a distinctive device and accompanied by an envelop marked on the outside with the nom de plume and containing the true name of the writer. The winning report will be the property of the association and will be published in *Military Surgeon*. The competition is open to all medical department officers former such officers, acting assistant and contract surgeons of the army, navy, public health service, organized militia veterans administration U S volunteers and the reserves of the United States and all members of the Association of Military Surgeons, except that no person shall be awarded a prize more than once in these contests.

CORRECTION

Dr Kolmer Has Not Resigned—Dr John A. Kolmer Philadelphia, has not resigned as professor of medicine at Temple University School of Medicine as reported in *THE JOURNAL*, July 13, page 127. The chair of medicine is now held jointly by Dr Kolmer and Dr Charles Leonard Brown, an arrangement that allows Dr Kolmer time to conduct research work at the university and at the Research Institute of Cutaneous Medicine.

After the Osteopaths' Fiasco

At a meeting of the council of the British Medical Association Dr Bone, who presented the report of the osteopathic committee, complained of the large expense incurred by the association, as well as by other professional organizations, in opposing the osteopaths' bill, which went simply to show that no such committee of investigation as was appointed by the house of lords should have been set up at all. He did not know whether there was any redress, but it seemed an inequitable phase of parliamentary procedure. The committee held twelve sittings extending over a period of six weeks and the association, as well as some of the other opposing bodies, was represented by lawyers. Sir William Jowett, the association's attorney, concentrated on clearly defined issues. He made the principal witness for the osteopaths admit that he could not claim state registration without proof of the scientific basis of their claims. He also secured repeated admissions that osteopaths claim to treat all varieties of disease, acute and chronic, that their theory is in conflict with scientific medicine and can give no reasonable explanation of many diseases, and that their theory conflicted with their practice. Before the evidence against the bill could be completed its promoter sounded the retreat, giving the reason that the committee was not competent to try the issue that had been raised as to the want of a scientific basis for osteopathy. This amounts to an admission that the committee should never have been appointed and that the medical bodies which opposed the bill should never have been put to such trouble and expense. But apparently they have no remedy. They must suffer for the want of intelligence of the members of the house of lords who gave the bill a second reading, leading to the appointment of the committee. Before the socialist issue dominated British politics, the reform of the house of lords was a constant demand of many liberal politicians. They ridiculed the hereditary chamber as indefensible. Why should a man legislate because he happened to be the son of a peer? He might be quite unfitted for the task. The fiasco of the osteopaths' bill gives a new point to this argument. It is noteworthy that in the house of commons, which, unlike the house of lords, is an elected and not a hereditary chamber, the attempts of the osteopaths have always failed. Since 1931 four bills were introduced for their registration and were all defeated. The minister of health sensibly took up the position that he could not countenance the registration of an inferior order of medical practitioners and that osteopaths who wanted registration should go through the same course and pass the same examination as physicians.

A point that has come out more strongly since the proceedings terminated is the confounding of osteopathy with bone setting in the press and in the public mind. This has been encouraged by the osteopaths in their desire "to cast the net" as widely as possible. Mr Blundell Bankhart, an orthopedic surgeon, has stated that he was informed that every one who supported the osteopaths' bill in the house of lords thought that he was voting for bonesetters. Bone setting, he points out in the *Lancet* is a much older procedure and is British while osteopathy is American. He might have added that the one is a proper and straightforward procedure (though the competence of its practitioners is in question), while the latter is a fantastic stunt. In a communication to the *British Medical Journal*, Mr Bankhart states that, while many osteopaths do a certain amount of straightforward manipulation of joints, that

is not osteopathy. Though this divergence from osteopathy in the practice of osteopaths has previously been pointed out, much confusion exists on the subject and was even shown by some of the medical witnesses at the inquiry.

Is Sugar Injurious?

It has been taught for a long time that sugar taken by children in the form of sweets promotes dental caries and also is injurious in other ways. On the other hand, some authorities deny this and consider sugar an excellent food. There seems to be no end to this controversy, which has been revived in the *Times*. Dr. A. C. Jordan, radiologist, who has written a good deal on 'intestinal stasis,' attacks the practice of giving sweets to children. He declares that they are not sufficiently masticated and therefore not digested by the enzymes of the saliva, and that they pass into the lower reaches of the intestine, where they undergo putrefaction and pour poisonous products into the general circulation, impairing the natural resistance of every organ and tissue. These views were vigorously attacked by Sydney W. Cole of the University of Cambridge School of Biochemistry. He points out that cane sugar (sucrose) is not digested by the salivary enzymes, so that no useful purpose would be served by prolonged mastication. Recent radiographic studies show that it passes through the stomach very quickly. It is rapidly absorbed from the blood in the form of dextrose and fructose, a rise in the blood sugar being obtained within ten minutes of taking an ounce. After one has taken as much as 4 ounces absorption seems to be complete in two hours, while the whole of a pint of raw milk does not leave the stomach in six hours.

Cole also points out that it is impossible for sugar to accumulate in the lower reaches of the intestine, and the lurid picture of it serving there as 'a perfect food for pathogenic microbes' is ridiculous. If soluble carbohydrates did exist in the intestine they would be converted by the intestinal bacteria into lactic and other acids the production of which inhibits the formation of toxins from proteins. In the Cambridge School of Biochemistry Cole teaches under the direction of his chief, Prof. Sir Gowland Hopkins, that cane sugar is a valuable foodstuff. It is absorbed much more rapidly and with much less digestive effort than an equivalent amount of cooked starch. He also claims that there is no satisfactory evidence that cane sugar is responsible for dental caries or for the increase in the incidence of diabetes. He tells the students that by mouth sucrose is the equal and probably the superior of the more expensive dextrose. He holds that it would be difficult to give a diet of adequate caloric value if sugar, sweets and jams were excluded. All young people engaged in strenuous exercise should have an ample sugar ration. It is well absorbed and has a unique effect in warding off exhaustion. Hence boat crews training on brown sugar do extremely well.

As regards dental caries the physiologist Prof. Sir Leonard Hill supports the view that sugar promotes caries. It might have been thought that, as sugar is the simplest of all foodstuffs, with a definite chemical constitution, and as it is obtained easily in the pure state, these questions should have been settled long ago.

Loss of Life in the Quetta Earthquake

The loss of life in the Quetta earthquake has been enormous. It is officially stated that the death roll, including the countryside, probably exceeds 40,000. Casualties among people of European birth amount to more than 190 killed and 240 injured. In Quetta itself, out of a population of 45,000, between 20,000 and 30,000 have been killed. The number of destitute refugees is 15,000 of whom many thousands are injured. The public health commissioner, Lieut.-Col. Russell of the Indian Medical Service, is proceeding to investigate the health situation in consultation with the local medical and public health authorities.

Some 30,000 Indians and 6,000 Europeans, including troops, have been fed in the refugee camps. Evacuation is still steadily proceeding. Salvage operations were commenced but had to be suspended for hygienic reasons, and in the interests of public health the city remains closed under guard. Only such operations as are consistent with safety and public health are being carried on. The area of the earthquake is estimated at 130 miles long and 20 miles broad. Besides Quetta and the towns of Kalat and Mastung at least 100 villages have been totally destroyed.

Tuberculosis and Pregnancy

At the March 15 meeting of the Société médicale des hôpitaux of Paris a paper on whether or not pulmonary tuberculosis is influenced by pregnancy was read by Professor Brindeau and his associates, followed by much discussion of the subject, in which leading phthisiologists of Paris took part. During a period of three years 230 cases were followed from a clinical and a roentgenologic point of view. Their conclusions were as follows:

1 A distinct influence on the evolution of a case of pulmonary tuberculosis can be observed only in multiple pregnancies that occur at short intervals in which the child is being nursed, thus weakening the maternal resistance. When tuberculosis shows signs of development during pregnancy, the association of the two conditions is only accidental. The tuberculosis was already incipient and would have developed even though pregnancy had not taken place.

2 One cannot deny the harmful influence of pregnancy on the evolution of tuberculosis. Such a stimulation of the pulmonary lesion is especially to be feared when the latter first presents itself at the beginning of the pregnancy, particularly if the pulmonary lesions are extensive, active and accompanied by febrile reaction. Twelve patients who presented signs of the acute bronchopneumonic type during the first months of pregnancy died. In three fifths of the cases in which there were evidences of the subacute type of tuberculosis at the beginning of pregnancy, death also occurred. In cases in which the lesions had been present for six months before pregnancy began a fatal outcome occurred in eleven of fifty-four. The harmful influence of pregnancy can be observed even in cases in which there is a slow evolution of the pulmonary lesions. Hence the problem with which one is confronted is to evaluate the intensity of the degree of development and destruction, on the one hand, and the period at which the last acute exacerbation has taken place. This is easy in the acute and subacute forms of recent lesions with cavity formation but is difficult in the chronic fibrous ulcerative forms, necessitating in the last named a visualization of the most recent former evolution and a periodic comparison of the films to determine the date of the last exacerbation as well as the temperature range and a general clinical balance, in order to determine when the next exacerbation is likely to occur. In nine of thirty-six cases there was a recrudescence during pregnancy in the fibrocalcifying type.

3 The harmful influence of pregnancy is most marked during the first three months and during the postpartum period. In the last months the tuberculosis seems to be less active. The latter observations hold true for pregnancy complicated by surgical tuberculous lesions.

In general, one can say that the harmful influence of pregnancy is proportional to the intensity and the length of time the destructive or caseating lesions have existed. The more acute, the worse the outlook. Before interruption of pregnancy is to be considered every possible measure should be

employed to control the pulmonary lesions. Twenty-nine patients with subacute evolutive and ulcerative pulmonary lesions treated adequately by artificial pneumothorax were able to be confined at term without perceptible aggravation of the pulmonary lesions. Four out of eleven women in whom the artificial pneumothorax treatment was inadequate died, and seven others required therapeutic abortion. The latter is indicated first, in recent, evolutive febrile cases in which the tuberculosis is concomitant with the pregnancy, and secondly, in the dense diffuse, fibrocaseous chronic type, and finally in cases in which there are ulcerative lesions and an acute exacerbation has occurred during the months immediately preceding the pregnancy.

In the discussion, Professor Sergent stated that every effort should be made to save the life of the mother by therapeutic abortion, when indicated, rather than attempt to deliver at term and lose the mother rather than the fetus. He did not agree with Professor Brindeau when the latter stated that the evolution of the pulmonary lesions at the beginning of the pregnancy was a mere coincidence. In 25 per cent of the cases he has examined a pregnancy or delivery had preceded by ten months the onset of the pulmonary lesions. The apparent improvement that is observed during the latter months of pregnancy is due to the upward displacement of the diaphragm, thus creating a sort of bilateral artificial pneumothorax.

Danger of Treatment of Epilepsy by Protein Shock

Marinesco and Kreindler of Bucharest reported a case at the March 15 meeting of the Societe medicale des hopitaux of Paris in which treatment by protein shock was applied in a case of severe convulsive attacks. The patient was a girl aged 18 years. The history of epileptic attacks dated back to the age of 18 months and they had been gradually increasing in frequency, duration and severity. The first injection, of 2 cc of sterilized milk, was not followed by any reaction. The second injection, of 5 cc., was followed about eight hours later by a series of attacks that were almost continuous. Death occurred thirteen hours after the injection. The temperature before death was 106 F.

The authors maintain that there is a direct relation between the epileptic attacks and the type of anaphylactic shock that follows injection of substances producing anaphylactic shock in animals. Clinically cases have been frequently observed of attacks following the ingestion of cheese, eggs, meat or milk. In certain cases of epilepsy there is a certain pathogenic relation between the attacks and spontaneous or artificially produced anaphylaxis. Bouche and Hustin have observed that frequently the attacks are preceded by vascular phenomena analogous to those seen in anaphylactic shock. Claude Tinel and Santenaise found that marked lack of balance of the neurovegetative mechanism existed in patients with epilepsy, hence it seems possible that a marked vagotonicity favors the occurrence of an anaphylactic shock. The authors had previously directed attention to the part played by the carotid sinus in the physiopathology of the epileptic seizure and it seems probable that the anaphylactic shock temporarily influences the excitability of the carotid sinus thus favoring the appearance of convulsive attacks.

Number of French and Foreign Medical Students in 1935

Dr Desfosses, editor of the *Presse medicale*, has published statistics on a subject that has caused a great deal of agitation in France. In 1935 there are 10,148 French and 3,021 foreign students in the various medical schools, hence more than a fourth of the total number of 13,169 are foreigners. Ten thousand French students are far more than are necessary to fill the needs for medical men in France and its colonies. Some

foreign countries, like Poland, now refuse to allow students to return to their native land to practice, and the same will soon be true of other countries that will not recognize a French diploma. The only method to decrease the plethora in the medical profession lies in the Portmann law, which aims to eliminate students during the first two years who cannot attain a certain grade in their examinations and who have not sufficient preliminary training.

Removal of Thyroid in Cardiac Insufficiency

At the March 27 meeting of the Societe nationale de chirurgie Lian, Welti and Facquet reported three cases of removal of the thyroid in cardiac insufficiency. The cardiologist Lian stated that he had studied the velocity of the circulation in fifty cases of cardiac insufficiency and found the velocity uniformly slower than in normal individuals. His observations confirm those of American investigators to the effect that the circulatory velocity is increased in hyperthyroidism and slower in myxedema. There is a distinct relation between the velocity of the circulation and metabolism. In cardiac insufficiency, Lian has found that the basal metabolism is often above normal, hence the hope to reduce the latter by removal of the thyroid in such patients. In the three cases in which Welti operated the complete thyroidectomy was followed by a marked improvement of the cardiac condition. The removal of the thyroid was not followed by any evidence of myxedema. In all three cases, medical treatment over a prolonged period had been of no avail. There has been a marked decrease in the dyspnea, in the size of the liver and in a return to normal of the venous pressure as measured with Villaret's apparatus. Operation in the first case was done five months and in the second and third cases three months before being reported. From a technical standpoint, care should be taken not to injure the parathyroids or the recurrent laryngeal nerve in leaving the posterior portion of the capsule.

Committee to Study the Use of the BCG Vaccine

A committee composed of bacteriologists and clinicians, whose chairman is Professor Marfan, has been appointed by the administrative council of the Pasteur Institute. Owing to the fact that several specialists in children's diseases have maintained that the BCG vaccine does not prevent the development of tuberculosis in infants, this committee aims to establish a close cooperation between the institute and those who are occupied in the application of the vaccine.

Masked Forms of Infarct of the Myocardium

Nine cases of the masked form of infarct of the myocardium were reported at the March 5 meeting of the Societe medicale des hopitaux by Laubry and Walser. In its typical form myocardial infarct is readily recognized by the severe anginal attack accompanied by digestive disturbances, fever, drop in blood pressure and signs of pericardial reaction. Roentgenoscopy and electrocardiography furnish confirmatory evidence but are not essential for the diagnosis. In some cases the pain is the outstanding and only symptom.

In a first group of atypical or 'masked' cases, either the pain in the chest was referred to the base of the lung, leading one to think of a pleuropulmonary congestion or there was pain in the right upper abdominal quadrant, as observed in cholelithiasis. In a second group there was a complete absence of any pain and the clinical picture was dominated by symptoms usually considered of lesser importance such as those of the type of a gastrointestinal intoxication or of a cardiac collapse of resistant cardiac insufficiency or of insular myocarditis with arrhythmia of sudden onset. It is not uncommon to find at the necropsy of elderly persons, who have never had anginal attacks, cicatrices indicating myocardial infarcts. The absence of pain depends on the location, rapidity of development and extent of the infarct.

The masked forms can at times be recognized by a pericardial friction sound. This is a finding of great value from a diagnostic point of view but is seldom present. More constant is a sudden drop in blood pressure. Roentgenography may reveal an aneurysm of the heart, but a great many infarcts are located deeply or on the anterior and posterior surfaces where they cannot be visualized. The electrocardiogram yields more useful information at an earlier period of the condition, but as yet it does not permit localization of the infarct.

New Regulations Affecting the Medical Profession

Until recently, ethical questions pertaining to the medical profession were settled by the medical societies or the "chambers of physicians" (*ärztekammern*). These functions have now been taken over by the *Kassenärztliche Vereinigung Deutschlands*. Some of the regulations are particularly emphasized. As a rule, no consent to the holding of office hours and to the paying of medical visits in a town in which other physicians are permanently located will be given, nor will consent be given to the holding of regular office hours in a town where there is no physician, or at two separate addresses in a physician's own place of residence. Panel physicians who have been holding special office hours in clinics or hospitals must give them up by July 1, 1935. In a building in which a general practitioner has established a practice, no other general practitioner may open up a practice. The same rule applies to specialists in the same field or in overlapping fields. Seasonal changes in one's place of practice are prohibited. The buying and selling of medical practices is prohibited, but a certain amount by way of compensation for the delivery of a physician's leasehold and equipment, including instruments, may be agreed on, in which transaction the local chairman of the *Kassenärztliche Vereinigung* must serve as an intermediary. In the future, no consent for the creation of a joint practice, or medical partnership, will be granted. However, the joint use of expensive diagnostic apparatus, such as x-ray apparatus, will be permitted. The age-old designation "general medical practitioner, surgeon and obstetrician," occasionally seen on physicians' signs, must be replaced, before July 1, 1935, by "praktischer Arzt" (general medical practitioner). The designation "praktischer homöopathischer Arzt" (homeopathic general practitioner) may be used only by those physicians who can furnish evidence of adequate training in this field, and who aside from certain exceptional cases, confine themselves to the homeopathic mode of prescribing. Until the question has been finally regulated, no special designations, such as "biologischer Arzt" (biologic physician) and "Naturarzt" (nature cure physician) will be permitted. No mention of a physician's hospital practice may be made on a physician's sign. Only the following specialties in medicine are officially recognized: (1) surgery, (2) gynecology and obstetrics, (3) orthopedics, (4) ophthalmology, (5) otorhinolaryngology, (6) dermatology and venereal diseases, (7) urology, (8) neurology and psychiatry, (9) roentgenology and phototherapy, (10) stomatology (for which a license to practice dentistry is necessary), (11) internal medicine, (12) gastrology, enterology and disorders of metabolism, (13) pneumology, (14) pediatrics. Designations of specialists which concern other branches or several of the branches mentioned are prohibited. It is not permissible to combine a designation for a specialty with that of a general practitioner. Likewise the designations "Badearzt" (spa physician) and "praktischer homöopathischer Arzt" are to be considered as referring to general practitioners and hence may not be combined with a title of a specialist. The period of special training for the following specialties is four years

surgery, gynecology and obstetrics, urology, internal medicine, gastrology, enterology and disorders of metabolism, pneumology and pediatrics, for the other specialties the period of special training is three years. Specialists in gastrology, enterology and disorders of metabolism, and also in pneumology, must spend two years of their special training in a department of internal diseases, pediatricians must spend one year in such a department. Candidates for recognition as specialists in urology must furnish proof of three years of clinical activity, in which an opportunity for training in general and urologic surgery was afforded. In addition, a candidate must have had one year's experience in a urologic polyclinic or with a specialist in urology. Service in other fields of medicine that are important for a given specialty may be counted up to one year. The training must be obtained at university clinics or in large hospitals of the German reich, or, by way of exception, at a German university clinic or in a large German hospital in a foreign country. The training must be in charge of recognized specialists, and the institution in which it is given must be suitably equipped for thorough and comprehensive special training. The training must extend to all fields of the specialty concerned and hence may not be given exclusively at special centers. Training received in polyclinics and in the office practice of recognized specialists must be discounted one half in point of time and can be counted only up to one year at the most. Service in welfare centers and in bureaus of health may not be counted. Approval of a candidate's claims for recognition as a specialist is left to the local chapter of the *Kassenärztliche Vereinigung*. Such recognition holds good for the whole territory of the reich. Before recognition can be given, candidates must show that they have the necessary special equipment for the practice of their specialty. Specialists must confine themselves, in the main, to their chosen specialty. Specialists who are directors of clinics or of large hospitals or hospital departments must confine themselves, as a rule, to office practice and to consultative activities. Specialists outside this group may make house visits. But they must ascertain whether there is a family physician who commonly treats members of the family and, in that case, they must insist on a joint visit and must reach an understanding with the family physician in regard to further treatment. The house visits of specialists must by no means take on the form of visits of a family physician, and particularly, other members of the family must not be advised or treated for their various ills. Pediatricians may treat only children under 14 years of age. In private practice, specialists should usually charge higher fees than are charged by general practitioners. A physician serving as a locum tenens of a specialist must be a specialist in the same field as the physician he is representing. These regulations, which go into effect immediately, take away from the *Deutscher Aerztevereinsbund* many of its most important functions. Even those physicians who do not belong to the *Kassenärztliche Vereinigung* are, in matters pertaining to professional ethics and to the recognition and conduct of specialists, subject to the decisions of the chairmen of the *Vereinigung* and must give heed to their instructions.

Congress of Psychotherapy

The specialists in psychotherapy ("seelenheilkunde" is the term now used in Germany) held their congress recently in Nauheim. Some time ago a reorganization of the society according to the racial views of the political party in power was effected, and it is held that psychotherapy, after breaking with the dominant ideas of the past epoch, which claimed Freud as its champion, has not lost its importance. Psychotherapy is not regarded as identical with psychoanalysis as set forth by Freud, and an endeavor is being made, after overcoming the dogmatic psychoanalysis, to create a new "seelen-

heilkunde," or psychotherapy, which will satisfy better the German type of mind. Under the chairmanship of C G Jung of Zurich, a number of papers were presented. Zimmer of Heidelberg reported the results of his studies on Indian views concerning psychotherapy. Van der Hoop of Amsterdam presented a paper on "The Personal, the Impersonal and the Hyperpersonal in Psychotherapy." Rümke of Amsterdam spoke on "The Particular Life Phase of the Patient in Connection with Treatment for a Neurosis." He emphasized the idea that psychotherapy is effective only when it considers at the same time what stage of development the patient has reached. From this thought he developed the principle of neuroses, for the various phases of life present widely different demands and every phase has its own peculiar reactions. From this fact result various tasks in connection with the application of psychotherapy, as the physician must take a different stand toward each phase of life and must bear in mind that man's problems vary greatly with each stage of his existence. In dealing with persons who are in the stage of growth and in their best strength, it appears proper to apply psychoanalysis in its complete form. At the turning point of life (age 40-50 years), psychotherapy as outlined by Jung is the sovereign method. In dealing with elderly persons, care should be taken not to insist too fanatically on the patient unburdening his mind completely, as he no longer possesses the elasticity of former days.

Göring of Wuppertal spoke on "The Chances of Success of Psychotherapeutic Treatment." He presented statistics that comprised all patients, over a period of four years to whom psychologic treatment was applied, organic cases and cases of schizophrenia and manic-depressive insanity having been excluded. The statistics (423 cases) revealed that the prospects of success are worse, the more constitutional factors are involved in a neurosis. On the other hand, more than 70 per cent of successes were attained when there was evidence of a marked influence of environment. With regard to the time necessary for the treatment, Göring found relatively short periods (from three to four months) adequate in most cases. He consistently refused to give treatment extending over several years. Other psychotherapists have had about the same experience, but the technic of the specialists varied considerably, since the personality of the physician played an important part.

Another main topic dealt with the teachability of psychotherapeutic science. In this connection it was emphasized that experience in general medicine is desirable and even necessary before practice as a specialist is begun and that psychotherapeutic training more than any other depends for its success on the individual aptitudes.

Professor Dr Wilhelm Kolle

The death of Professor Dr Wilhelm Kolle, who is well known as having been for many years director of the Staatsinstitut für experimentelle Therapie and the associated Georg Speyer-Haus in Frankfurt on-Main, at the age of 66, has been announced. After receiving his training as assistant physician at the Berlin Robert Koch Institute for Infectious Diseases he conducted a scientific expedition in South Africa under the auspices of the government of South Africa and later an expedition in the Sudan under the commission of the Egyptian government. In 1906 he was summoned to the University of Bern, as ordinarius in hygiene and bacteriology and became in 1917 the successor of Paul Ehrlich in Frankfurt on Main. Kolle manifested great pride in the fact that he was a pupil of Robert Koch. In collaboration with R. Pfeiffer he worked out the bases for immunization against cholera and typhoid and also performed the first immunizations on man. Collaborating with Wassermann he established the evaluation of the

meningococcus serum and also of the dysentery serum, the plague serum and the arsphenamine preparations. His researches on symptomless syphilis are well known. Kolle was a member of numerous scientific bodies, also a member of the standardization commission of the health committee of the League of Nations. Arsphenamine therapy, the experimental bases of which Kolle had taken over from his predecessor Ehrlich, he developed further in a successful manner.

Rioting Students Reprimanded

In view of the continuous antisemitic disturbances, chiefly at the faculty of medicine of the university, the universities called a conference with the aim of establishing order. The conference established the fact that the disturbances perpetrated against fellow Jewish students originate partly in the university and student demands, and partly in social and political causes. Formerly the interuniversity council limited the number of students, not on a religious or racial basis but on a basis of individual fitness and competence. A committee was appointed to establish the program of examinations to be passed before enrolment. The official communique published in connection with the limitation of the number of students contains the following paragraphs:

- 1 As an excessive number of students endangers adequate training, the interuniversity council will in the future fix the maximal number of students enrollable four months prior to the opening of the sessions.
- 2 First year enrolment will be subject to a special examination, the conditions of which will be stabilized by the ministry of instruction and by the board of the universities.
- 3 Owing to the fact that, in consequence of this measure, the income of the universities will be reduced, the ministry will increase the subsidies due to the universities.
- 4 The attendance at lectures, seminars, laboratories and institutes is compulsory for every student.
- 5 Any student who within two years does not successfully pass the examinations prescribed for one year will be excluded as unfit and will not be enrolled in any of the inland universities.

These measures are intended partly to reduce the number of students and partly to remove students who spend their time in street demonstrations and in politics, thereby neglecting their studies.

Induced Abortion and the New Rumanian Penal Code

The parliamentary committee entrusted with the preparation of the new penal code accepted the following draft. Section 480: Whoever performs or assists in the interruption of the normal course of gestation commits the crime of abortion and is liable to punishment as follows: 1 If the crime is committed without the consent of the woman, the punishment is imprisonment for from three to five years. If the woman succumbs in consequence of the operation, the punishment is from seven to ten years imprisonment. 2 If an unmarried woman performs the operation on herself or causes the operation to be done by another person she is liable to punishment of from three to six months in prison, if she is a married woman, the prison term is from six to twelve months. Section 481: The same punishment is due for the attempt of this crime. Section 482: If the operation is performed by a physician, no punishment is due in the following cases: 1 When the pregnancy is the result of criminal violence. 2 If the life of the woman is in danger as shown by the physician performing the operation and also by another physician prior to the operation. 3 If the pregnant woman was insane, which fact was established also by another physician prior to the operation, and if the legal representative or guardian of the woman gave his consent.

in an authentic form. In such cases the physician performing the operation is obliged to make notification of the case within twenty-four hours to the competent magistrate.

The Control of Foreign Graduates

While the proportion of Aryan young men studying abroad is not more than 0.5 per cent, that of Jewish lads is considerably higher. They take refuge in foreign universities. It is not a luxury on their part but rather a restraint. Studying abroad is an expensive undertaking. They have to attend lectures and pass examinations in a foreign language. These young doctors then have to come back to Rumania after graduation, because no European country allows them to practice.

The interuniversity council has adopted the following resolution in regard to foreign diplomas. The notification of diplomas acquired abroad, when there is a reciprocity between the respective country and Rumania, can take place only in those cases in which the permanent public instruction committee established the right of the candidate to study abroad and provided the applicant studied the number of years required in Rumania and passed all examinations required at Rumanian universities. The council, in certain cases, may require the applicant to repeat certain examinations. The application for notification must be sent to the ministry of public instruction, which passes it on to one of the inland universities.

BUENOS AIRES

Long Distance Transportation of Blood for Transfusion

A transfusion department was organized by Drs. R. Palazzo and J. Tenconi in the Hospital Italiano of Buenos Aires, more than a year ago, with the aim of supplying preserved blood that can be transported long distances for transfusion. The main reason for establishing the department was to have at hand a stock of cells and plasma already classified for emergencies. The results have been satisfactory. Drs. Palazzo and Tenconi have sent suspensions of erythrocytes in a dextrose solution to colleagues in Rio de Janeiro, Bordeaux and Pavia, in order to prove the possibility of keeping and transporting erythrocytes. Dr. Servant of Bordeaux performed without any inconvenience transfusions with erythrocytes that had been taken from the blood of persons in Buenos Aires twenty days before. The methods of Drs. Palazzo and Tenconi are based on the studies of Rous.

Antituberculosis Federation

The several separate tuberculosis societies recently merged into one organization, the Federation Against Tuberculosis. The alliance is voluntary, being neither legal nor administrative, and was accomplished by the combined efforts especially of Drs. C. Mammi of the Sociedad de Fisiología of Buenos Aires, G. Araoz Alfaro of the Liga Argentina de la tuberculosis, G. Sayago of the Instituto de Fisiología of the University of Córdoba, A. Raimondi of Buenos Aires and the members of the different beneficent societies and hospitals of the country. The national committee of regional hospitals and asylums voted for the construction of four new tuberculosis sanatoriums simultaneously with the fusion of the antituberculosis centers.

Ventriculography with Iodized Oil

Drs. M. Balado and R. Carrillo of Argentina in an article published in *La semana medica*, March 7, emphasize the diagnostic value of ventriculography with iodized oil. They regard this method as safer than Dandy's encephalography with injection of air and Egas Moniz's arteriography. The latter two methods make difficult the visualization of lesions in the posterior cranial fossa. The authors have performed more than 303

ventriculographies with iodized oil since 1928. In seventy cases of this group they were able to make an anatomic study of the brain post mortem. Ventriculography with iodized oil is, they believe, harmless and permits the visualization of the third and fourth ventricles, the Sylvian aqueduct and the foramen of Monro. The authors discuss in detail the technique. They believe that a diagnosis of exact localization of the lesion in the brain can be secured in 90 per cent of the cases by the injection of air and in 100 per cent by ventriculography with iodized oil either by itself or combined with the injection of air.

Special Lectures

Dr. Policard of Lyons, France, delivered lectures on the histophysiology of the lung, silicosis, osteogenesis and spectrography, at the Faculties of Medicine of Buenos Aires, Rosario and Montevideo, during May and June.

Dr. B. A. Houssay has been invited to deliver the Dumbarn lecture at Harvard, the Hanna lecture at Cleveland, the Harvey lecture at New York and some other lectures at the Academy of Medicine of California and at Stanford University.

Personals

The following appointments have recently been made. Drs. Belou, correspondent member of the Academia Chilena de Ciencias Naturales, M. R. Castex, B. A. Houssay and C. Bonorino Udaondo, honorary members of the Academia de Medicina of Mexico, Arce, Vaccarezza, Bosch Arana and Bonarino Udaondo, honorary members of the Academia de Medicina of Rio de Janeiro, B. A. Houssay, honorary member of the Physiological Society of Great Britain, F. de Paula Miranda of Mexico, A. Turenne of Montevideo and A. Policard of Lyons, corresponding members of the Academia Nacional de Medicina of Buenos Aires. Drs. E. Savino and R. Sammartino were given scholarships from the Guggenheim and Devoto foundations for studies on public health at Harvard, and on cancer in Germany, respectively.

São Lourenço Balneary

The São Lourenço Balneary, recently opened in Minas Geraes, is the first of its kind in the South American countries. There are modern installations for bathing in natural gaseous waters, the therapeutic value of which has been demonstrated in several pathologic conditions. There are also showers and departments for massage. São Lourenço Balneary has twenty-four private baths. About thirty persons can take baths in an hour. A physician is the technical director of the balneary.

First Brazilian Congress Against Cancer

At the first Brazilian Congress, organized by the Sociedade de Medicina e Cirurgia of Rio de Janeiro, with the collaboration of the medical societies of the country, at Rio de Janeiro, the official topics will be: In the medicosocial section (1) mortality from cancer in Brazil, and (2) actual resources for the anticancer crusade. In the clinical section: clinical aspects of precancer (synthesis). In the pathologic section (1) classification of cancer, and (2) localization and dissemination of cancer in Brazil. The problem of cancer in Brazil will be discussed from several angles. The topics will be presented by two official speakers, one resident at the federal district and the other resident at any of the states of the country, thoroughly discussed by them and then by the attendants to the congress, including those who were previously registered for attendance. The Associação central brasileira de luta contra o cancer will represent, after the congress, the organized body for the crusade against cancer and will have branches in the various states of the country.

A Home for Needy Brazilian Physicians

The building of the institution La Casa del Medico was recently inaugurated. It was constructed with donations from all Brazilian physicians on a site given by the late Dr. Felicio Torres. It is a three story structure at present but has been built to allow for the construction of five additional floors. The accommodations meet all the requirements for comfort and beauty expected in modern living. Its purpose is to house physicians who are in need of a comfortable home. Those who can pay are given special apartments on the first and second floors. Those who cannot are given apartments on the third floor. There are special wings for old and invalid physicians who can remain there as long as they wish. The Brazilian syndicate of physicians is in charge of the administration of the building. Prominent Brazilian physicians attended the inauguration ceremonies.

Marriages

JOHN R. RODGER, Boyne City, Mich., to Miss Katherine Johnston of Greeneville, Tenn., in New York July 3

FLOYD ALTON MCCANNON Payne Ohio, to Miss Ardola May Lechner of Ossian, Ind., May 22

ELBERT ERVIN MUNGER JR., Spencer, Iowa, to Miss Millicent Christner of Rosamond, Ill. June 29

RAIPH J THOMPSON to DR. BERTHELLA E JARVIS, both of Huntington Park, Calif., recently

JAMES PORTER BAKER JR. to Miss Louise Herbert Rogerson both of Richmond, Va., June 8

RALPH F HELZERMANN, Tecumseh, Mich., to Miss Edna A Mackenzie of Adrian, June 19

TOM VANN WILLIS Brunswick, Ga., to Miss Ouida Jayne Temples of Statesboro, June 8

SAMUEL R ZOSS, Cleveland, to Miss Sadye R Hoffman of Youngstown Ohio June 16

EVERETT C FOX, Dallas, Texas to Miss Ella Gertrude Boyce of St Louis June 5

CLYDE O ANDERSON, St Petersburg Fla., to Miss Eileen Masters of Tampa, June 20

LEON BANACH to Miss Marguerite N Fitzgerald both of Jersey City, N J, June 15

WILLIAM W SHORTAL to Miss Minnie Bell Graham both of Dallas, Texas, June 14

JUDSON D DOWLING to Miss Fleta McWhorter both of Birmingham, Ala June 8

HARRY E BACON to Miss Althea Hildegard Wahle both of Philadelphia, June 21

THOMAS OSCAR VINSON, Macon Ga., to Miss Roesel Stanford of Augusta June 6

RAPHAEL J HENNES Oxford Iowa to Miss Alberta Bauer of Iowa City, April 29

PHILIP E. BLACKERBY JR Louisville Ky to Miss Clara Mae Hartmetz, June 1

JOHN H BOWLES to Miss Mary Joanna Kelsey both of Muncie, Ind. June 14

DONALD A COVALT to DR. NILA GALE KIRKPATRICK both of Muncie Ind., recently

FRANCES M JOHNSON, Marion Ind. to Mr Alyn G Price of Cleveland, recently

ROBERT PHELPS BARDEN to Miss Virginia Gates both of New York June 15

ISRAEL ROBERT FRANK Boston to Miss Vera Witkin of Brookline July 17

HAROLD OYER, Angola, Ind to Miss Doris Bauer of Fort Wayne, June 7

VICENTE R LAZO to Miss Alice Bennett both of Shelburn Ind May 18

JAMES A WIGLEY, Mulberry Ark to Mrs Lillian Bencux May 18.

Deaths

Benjamin S Warren ☉ Medical Director, U S Public Health Service, Chevy Chase, Md., Tulane University of Louisiana Medical Department, New Orleans, 1891, appointed assistant surgeon in the U S Public Health Service in 1900, passed assistant surgeon in 1905, surgeon in 1912, assistant surgeon general in 1918 and medical director in 1930, professor of hygiene, St Louis University School of Medicine, 1909-1911, sanitary adviser to the U S Commission on Industrial Relations 1913-1915, medical officer of the U S Employees Compensation Commission in 1917, author of various government bulletins and articles relating to open air schools, and relation of wages to public health, aged 63, died, May 19, in the U S Marine Hospital, Baltimore of cerebral hemorrhage.

John Westley Wright, Columbus, Ohio, Cincinnati College of Medicine and Surgery, 1873, member of the Ohio State Medical Association and the American Academy of Ophthalmology and Oto-Laryngology, professor of ophthalmology, Ohio Medical University and Starling-Ohio Medical College, 1891-1910, formerly emeritus professor of clinical ophthalmology at the Ohio State University College of Medicine, Civil War veteran, at one time on the staff of the Protestant Hospital, now known as the White Cross Hospital, author of 'A Textbook of Ophthalmology', aged 92, died, May 23.

James Granger Poe ☉ Dallas, Texas, University of Tennessee Medical Department, Nashville, 1894, since 1919 instructor in anesthesia, Baylor University College of Medicine and Dentistry, demonstrator in anatomy at his alma mater, 1895-1896, member of the Associated Anesthetists of the United States and Canada, chief anesthetist to the Baylor Hospital, author of 'Modern General Anesthesia', aged 62, died, June 15, of coronary occlusion.

Paul Colson Perry, Jacksonville Fla., College of Physicians and Surgeons, Baltimore, 1897, past president of the Florida Medical Association and the Duval County Medical Society, formerly on the staffs of St Luke's, Duval County and St. Vincent's hospitals, aged 60, died, June 5, in a hospital at Richmond, Va., of pulmonary embolism, following an operation.

John Port Shaw, Brockton Mass. Trinity Medical College Toronto Ont., Canada, 1886, member of the Massachusetts Medical Society, for many years on the staff of the Brockton Hospital, aged 76, died, June 5, of myocarditis, arteriosclerosis and nephritis.

Eugene Arthur West, Chicago, Marquette University School of Medicine, Milwaukee, 1913, member of the Illinois State Medical Society, aged 50, on the staff of the Frances Willard Hospital, where he died, June 18, of pulmonary edema and cerebral hemorrhage.

Parker U Wagoner ☉ Carlisle, Pa., Temple University School of Medicine, Philadelphia 1911, past president of the Cumberland County Medical Society, served during the World War, aged 48, on the staff of the Carlisle Hospital where he died, June 14.

Perry Woolery, Bedford, Ind. Louisville (Ky) Medical College 1897, member of the Indiana State Medical Association, past president of the Lawrence County Medical Society, aged 65, died May 22, of arteriosclerosis and cerebral hemorrhage.

Charles Carr Morrison, Bar Harbor Maine, Hahnemann Medical College of Philadelphia 1883, member of the Maine Medical Association on the staff of the Mount Desert Island Hospital, aged 78, died, May 5, of lobar pneumonia and acute appendicitis.

Julius Niemack ☉ Charles City Iowa Georg-August-Universität Medizinische Fakultät Göttingen, Prussia, 1891, fellow of the American College of Surgeons, surgeon to the Cedar Valley Hospital, aged 75, died May 5, of cerebral thrombosis.

Asa L T Williams ☉ Vandalia, Ill., Marion-Sims College of Medicine, St Louis 1898, president and formerly secretary of the Fayette County Medical Society, on the staff of the Mark Greer Hospital, aged 64, was found dead June 13.

Joshua Zadok Sexton, Waco Texas Vanderbilt University School of Medicine Nashville, Tenn., 1897, member of the State Medical Association of Texas, aged 63, died June 3, in a local hospital of cerebral hemorrhage and hypertension.

Bayard Taylor Mousley, Walpole, N H Baltimore Medical College, 1905, served during the World War, formerly member of the state legislature and school board, health officer of Walpole, aged 56, died May 30, of coronary thrombosis.

Thomas A Wash, Harrodsburg, Ky, Hospital College of Medicine, Louisville, 1903, member of the Kentucky State Medical Association, mayor of Harrodsburg, aged 56, died, June 12, of chronic myocarditis and arteriosclerosis

Albert Edward Smethurst, Philadelphia, Medico-Chirurgical College of Philadelphia, 1898, member of the Medical Society of the State of Pennsylvania, aged 63, died, June 12, in the Episcopal Hospital, of coronary thrombosis

James A Stevens, Easton, Md, Jefferson Medical College of Philadelphia, 1882, formerly member of the state board of medical examiners, aged 81, died, June 8, of endarteritis obliterans and gangrene of the left foot

Charles H Christian, Fulton, Mo, St. Louis Medical College, 1890, member of the Missouri State Medical Association, past president of the Callaway County Medical Society, aged 74, died, May 9, of arteriosclerosis

Martin Luther Bradley, Springfield, Tenn, Vanderbilt University School of Medicine, Nashville, 1882, member of the Tennessee State Medical Association, aged 75, died, June 26, of chronic valvular heart disease.

John Henry Rice, Hopkinsville, Ky, Hospital College of Medicine, Louisville, 1904, member of the Kentucky State Medical Association, aged 64, died, June 7, of gangrene of the left hand and anemia

Alfred W Pearson, Gold Beach, Ore, Hahnemann Medical College and Hospital, Chicago, 1888, aged 72, died, April 27, of shock and inanition, following an operation for carcinoma of the bile ducts

George R Rohrer @ Lancaster, Pa, University of Pennsylvania Department of Medicine, Philadelphia, 1880, on the staffs of Lancaster General and St. Joseph's hospitals, aged 81, died recently

Edward Porter Webb @ Crestview, Fla, Georgia College of Eclectic Medicine and Surgery, Atlanta, 1902, past president of the Walton-Okaloosa Counties Medical Society, aged 63, died, May 26

Elizabeth Matthews, Springfield, Ill, Woman's Medical College, Chicago, 1890, served with the American Red Cross during the World War, aged 73, died, June 9, of cerebral hemorrhage.

Richard Henry Moers, Houston, Texas, Tulane University of Louisiana Medical Department, New Orleans, 1910, aged 49, died, May 24, in a local hospital, of embolism and coronary thrombosis

Albert C Stephens, Barren Springs, Va, University of Maryland School of Medicine, Baltimore, 1894, member of the Medical Society of Virginia, aged 65, died, May 15, of angina pectoris

Robert Finney Miller, Brenham, Texas, Tulane University of Louisiana Medical Department, New Orleans, 1893, served during the World War, aged 69, died, April 5, in a local hospital

Milton Walborn Phillips, Chapman Quarries, Pa, Medico-Chirurgical College of Philadelphia, 1906, member of the Medical Society of the State of Pennsylvania, aged 65, died, May 28

Fabian Blanchard, Lindsay, Ont., Canada, University of Toronto Faculty of Medicine, 1893, member of the Associated Anesthetists of the United States and Canada, aged 64, died, May 4

Mendes Smyle Wechsler @ New York, University and Bellevue Hospital Medical College, New York, 1919, aged 39, died, May 25, of acute encephalitis and bronchopneumonia.

Charles Arthur Walter, Glenside, Pa, Jefferson Medical College of Philadelphia, 1910, member of the Medical Society of the State of Pennsylvania, aged 52, died, April 25

Marvin Jesse Arthur Miller, Minneapolis, University of Minnesota Medical School, Minneapolis, 1935, aged 24, was accidentally drowned, May 30, in Lawrence Township

Harry Clemmens Payne @ Pella, Iowa, Keokuk Medical College, 1897, president of the Marion County Medical Society, aged 64, died, June 23, of carcinoma of the lung

Henry G Maxey, Woodville, Ga., Georgia College of Eclectic Medicine and Surgery, 1913, aged 43, died, June 14, in a hospital at Atlanta, of furuncle and erysipelas

Martin John Nolan, Cheyenne, Wyo, University of Nebraska College of Medicine, Omaha, 1919, aged 41, died, April 11, in Rochester, Minn., of duodenal ulcer

Simon F Earnest, Hummelstown, Pa, University of Pennsylvania Department of Medicine, Philadelphia 1891, aged 68, died, May 6, of uremia due to prostatic disease

George Napoleon Gaboury, Springfield, Mass., Harvard University Medical School, Boston, 1910, aged 51, died, June 4, of angina pectoris and coronary thrombosis

John William Patterson, Oconee, Ill, College of Physicians and Surgeons of Chicago, 1893, aged 67, died, June 7, of abscess of the middle ear and meningitis.

Earle Stanley Prindle, Portland, Ore., Hahnemann Medical College and Hospital, Chicago, 1893, aged 65, died, May 26, of coronary thrombosis and angina pectoris

Hugo Gutmann @ Schenectady, N Y, Medizinische Fakultät der Friedrich-Wilhelms Universität, Berlin, Prussia, 1896, aged 62, died, June 3, of angina pectoris

Mary J Whittett, Anchorage, Texas (licensed in Texas under the Act of 1907), member of the State Medical Association of Texas, aged 81, died, May 24

James A Lester, Fayetteville, Ga, Atlanta Medical College, 1894, member of the Medical Association of Georgia, aged 65, died, June 24, of angina pectoris

William T Mahon, St. Louis, College of Physicians and Surgeons, Keokuk, Iowa, 1880, formerly mayor of Chamoss, Mo., aged 82, died, May 13, of pyelitis

Edward Clint Allen, Wayland, Iowa, St. Louis College of Physicians and Surgeons, 1898, member of the Iowa State Medical Society, aged 63, died, May 19

Leon B Gordon, Williamsville, Vt., University of Vermont College of Medicine, Burlington, 1906, aged 59, died, June 10, of cerebral hemorrhage.

Edward Benedict Taylor @ Huron, S D, Northwestern University Medical School, Chicago, 1894, aged 66, died, June 2, of cerebral hemorrhage.

Robert Arthur Mathew, La Veta, Colo, Rush Medical College, Chicago, 1897, aged 62, died, May 20, in the La Veta Hospital, of chronic nephritis

Harry Haynes Rowland @ New York, Columbia University College of Physicians and Surgeons, New York, 1903, aged 58, died, May 18.

James Angus Monroe, Wheeling, W Va, Eclectic Medical Institute, Cincinnati, 1882, aged 82, died, May 30, of coronary occlusion

Isaac Singleton Garthwaite, Santa Monica, Calif, University of Maryland School of Medicine, Baltimore, 1896, aged 70, died, May 18

Fred Young, Demorest, Ga, Georgia College of Eclectic Medicine and Surgery, Atlanta, 1908, died in April, of cerebral hemorrhage

Isaac Hale Rathbun, Spring Valley, Ill, Rush Medical College, Chicago, 1878, aged 84, died, June 11, of carcinoma of the larynx.

Joseph S Martin, St. Martinsville, La, Tulane University of Louisiana Medical Department, New Orleans, 1895, aged 62, died, May 15

George H Brannon @ Manhattan, Ill, Hospital College of Medicine, Louisville, Ky., 1889, aged 72, died, May 15, of heart disease.

George Chester Pope, San Marino, Calif., University of the City of New York Medical Department, 1889, aged 73, died, May 4

Edward A Schnell, Greenwich, Conn. (licensed in Connecticut in 1893), aged 67, died, June 12, of cerebral hemorrhage.

Paul Jean Woolsey, Kalamazoo, Mich, Detroit College of Medicine, 1896, aged 69, died, June 21, of carcinoma of the prostate.

Albert J Fisher, Toronto, Ont., Canada, Queen's University Faculty of Medicine, Kingston, 1887, aged 76, died, May 16

Edmund Emmet O'Donnell, New York, Yale University School of Medicine, New Haven, Conn., 1898, aged 59, died, May 16

Ella Batchelder Lefavour Dean, Beverly, Mass., College of Physicians and Surgeons, Boston, 1920, aged 64, died, May 6

Charles Albert Mooers, Attleboro, Mass, New York Homeopathic Medical College, 1876, aged 87, died, April 25

James D Weddell, Tyro, Kan., Washington University School of Medicine, Baltimore, 1872, aged 86, died, in May

Winifred M Byrne, San Francisco, California Medical College, San Francisco 1896, aged 76, died, May 1

Irvin Sheppard, Sheridan, Ark. (licensed in Arkansas in 1903), aged 67, died, June 16, of encephalitis

Bureau of Investigation

SIROIL

A "Patent Medicine" for Psoriasis

"Siroil" is a "patent medicine" sold on the mail-order plan by the Siroil Laboratories, Inc., of Detroit. The concern is said to be a Delaware corporation organized in July, 1934. One Ben Kaufmann was reported to have been originally the president of the Siroil Laboratories and to have connected with him two sons, Irvin (who is now president) and Marvin (who is vice president). Among the directors there are said to be Frank V Martin, Dr R J McClellan and S Meisner. Mr Ben Kaufmann is reported to have been in the cleaning and dyeing business for some years and later to have incorporated a jewelry concern that did business on the installment plan, and also to have been vice president of a liquor distributing company. Irvin Kaufmann is reported to have been employed by the jewelry concern already mentioned. Frank V Martin it appears, is in the advertising business. Dr McClellan is reported to be a Detroit physician, and Mr Meisner is said to have formerly been engaged in the retail jewelry business in Columbus, Ohio.

which the dermatologist is confronted. Yet it is equally well known by medical men that many cases of psoriasis clear up in a remarkable way with treatment. However, the likelihood of recurrence is ever present.

More recently the Siroil concern has brought out two additional products "Ecoil" for eczema and "Siroil Shampoo the Perfect Hair Conditioner."

Because of the number of inquiries that the Bureau of Investigation has received regarding Siroil, the Chemical Laboratory of the American Medical Association was asked to analyze the preparation. The chemists' report follows:

CHEMISTS' REPORT

"Two original bottles of Siroil (Siroil Laboratories 1214 Griswold St., Detroit, Mich.) were submitted to the A. M. A. Chemical Laboratory for examination. The specimens were not identical in appearance. In general, the preparation appeared to consist for the greater part of a yellow oil together with a small amount of a suspended material which had settled to the bottom of the bottle. No information concerning the composition of Siroil was given by the manufacturer on the label or in the accompanying circular. On shaking, the mixture emulsified, on long standing, a yellow liquid separated and an insoluble material settled to the bottom of the container. When centrifuged, the product separated into two separate liquid layers and a solid. The upper layer was a yellow iridescent oil, indicative of an unbleached mineral oil, the lower layer was a colorless liquid, suggestive of water. The solid material was mostly 'centrifuged' to the bottom of the tube, but some solid substance remained between the two layers. The product had an odor of phenol. The reaction toward moistened litmus paper was alkaline.

"Qualitative tests for heavy metals, such as mercury, salicylic acid, chrysarobin and ammonium compounds were negative. A large amount of mineral oil (suggestive of an unbleached liquid petrolatum) was found. Tests also indicated the presence of phenol sodium chloride (probably as dairy salt), glycerine, water, and a very small amount of saponifiable material, and a small quantity of a waxy substance.

"The specific gravity was found to be 0.894 (approximately 0.9). On heating a specimen for six hours on the steam bath, the loss in weight was approximately 10 per cent. Further investigation indicated approximately 78 per cent liquid mineral oil and the presence of sodium chloride (approximately 0.2 per cent), phenol (approximately 0.15 per cent), a saponifiable material and an insoluble wax-like substance (suggestive of beeswax) approximately 0.25 per cent.

"The foregoing examination indicates that Siroil consists essentially of an unbleached mineral oil roughly 16 parts, water about 3 parts, glycerine approximately $\frac{1}{10}$ part, and $\frac{1}{10}$ part of each phenol and sodium chloride (salt), and $\frac{1}{10}$ part of a saponifiable material and beeswax.

"A preparation having essentially similar properties to those of Siroil may be prepared as follows:

Liquid mineral oil (yellow)	800 cc
Dairy salt	0.5 Gm
Phenol (crystals)	0.5 Gm
Glycerine	0.8 cc
Beeswax (yellow)	0.5 Gm
Water	170 cc*

* While tests indicated a very small amount of saponifiable matter—probably a fatty oil—it was not deemed worth while to identify the saponifiable matter. Tests indicate that if present it was in amounts less than one per cent.

"Dissolve the dairy salt and phenol crystals in the glycerine and water, add the mineral oil and beeswax, finally warm and shake.

According to the advertising, Siroil is 'a positive relief for psoriasis.' In circular letters sent out by the Siroil Laboratories, signed "I G Kaufmann," the sufferer from psoriasis is told "No matter how difficult or longstanding your case may be, Siroil will give you surprising relief." In advertisements published in the New York Times (a newspaper which, before the depression did not carry "patent medicine" advertising) we read:

Siroil applied externally to the affected area causes the scales to disappear, the red blotches to fade out and the skin to resume its normal texture.

Yet the Siroil concern declares that 'We are making no extravagant claims for Siroil.'

The alleged genesis of Siroil falls into one of the well-known patterns common to "patent medicine" exploitation. The public is told that "an outstanding chemist who had psoriasis and was 'unable to obtain relief from the best skin specialists' began the inevitable 'intensive research in an endeavor to find a cure. After six years he is alleged to have developed the preparation which 'successfully treated his own condition.' This was born Siroil.

It is unnecessary to tell physicians that there is probably no skin disease more difficult to treat satisfactorily than psoriasis. The condition is frequently among the most intractable with

for PSORIASIS

LEARN ABOUT SIROIL

THE GUARANTEED RELIEF

Siroil, the new relief for psoriasis has brought expressions of gratitude from men and women throughout the country. You owe it to yourself to try it. Unless it relieves your condition within two weeks—and you are the sole judge—this treatment costs you absolutely nothing. Our guarantee covers that fully Siroil applied externally to the affected area causes the scales to disappear, the red blotches to fade out and the skin to resume its normal texture.

SIROIL LABORATORIES
1214 Griswold St., Detroit, Mich.

Reports have come in from persons who have tried Siroil and are enthusiastic about it. On the other hand, a Philadelphia woman writes that after using Siroil "a rash is beginning to appear on my body. A Pennsylvania physician reports that a psoriasis patient of his used Siroil and "developed an eruption on the neck, face and hands characteristic of dermatitis venenata. A Massachusetts physician reports that a patient of his used Siroil and developed a severe rash wherever it came in contact with her skin."

In other words the letters to the Bureau of Investigation reflect what one would expect to be the opinions on a preparation of this character. Siroil occasionally helps occasionally harms and frequently does neither one nor the other.

A PROBLEM IN DIETETICS

To the Editor — Anent the timely article of Alvarez and Hinshaw in *THE JOURNAL* of June 8 on "Foods That Commonly Disagree with People," may I be allowed to make a comment or two?

I have observed in several of my patients and in my own self that many of the so-called offending foods turn on us, so to speak, because they are not eaten in a state of perfect freshness or after being naturally ripened. This is especially true of the vine-producing vegetables and fruits such as cucumbers and cantaloupes.

If such articles are served "fresh from the vine" and not from market shelves, where they may have reposed for hours and days, there will be noticed a total lack of digestive disturbance or at any rate a greatly reduced upset. Doubtless chemical changes take place in such products of the soil after they are separated from the mother stem, and there would seem to be but one moral to draw, viz., "Own your own garden." With modern refrigeration it is a simple problem to have the two 'offenders' mentioned thoroughly chilled for fifteen minutes before they are served, and all will be well with the eater.

I have made the same observation regarding the use of sweet corn, for here too its preparation for the table should be expedited after its plucking, just as one would snatch a rainbow trout from the cold, limpid stream and throw it almost writhing on the savoring broiler.

There is no standstill in nature's kingdoms, either vegetable or animal, and it does not hesitate to visit punishment on many an eater of foods that are improperly or insufficiently matured or tardily prepared for consumption. The Englishman may prefer his beefsteak or lamb chop very "high," but he surely flirts with digestive disturbances in so taking it.

Undoubtedly much of the discomfort or distress attending an indulgence in shell-fish is primarily due to the fact that toxins develop during the period following its removal from native haunts to the hour of its consumption. It would seem to me that the chemistry of many foods will yet bear closer study regardless of their content in vitamins.

Why does the lowly onion "in the raw" so frequently retrace its course upward from stomach to palate, whereas, if eaten after floating on waves of acetic acid or after a thorough steaming and delicious creaming, it stays "put"? Chemical and physical changes, both gross and fine! Similarly, and yet paradoxically, on the contrary raw cabbage versus boiled cabbage. Again, compare the result of eating under-ripened fruits, such as the highly thought of banana, with that following the partaking of the same fruit thoroughly ripened on the tree. Similarly with the citrus family.

These points may be looked on as unpractical, but they must be taken into account in any logical discussion of dietetics.

When one stops to consider the excellent quality of milk as a culture medium, is it to be wondered at that so many individuals apparently in normal or average health complain of this food in their diets? What though the bacterial count is low at the laboratory or that pasteurization has been done, what is really known as to the changes that have taken place from the time of its withdrawal from the giver until it is consumed? There is nothing to govern one's decision as to its fitness for use except the taste of it, and this may be far misleading.

The same observation must be equally true of so unstable a product as the altogether worthy egg, which when "gathered" from the still warm nest of the cackling biddy is food fit for the gods.

I recognize in this discussion a factor known as allergy so far as the protein content of foods is concerned, but I believe

that the term is being used to cover a big bit of ignorance regarding the composition of a strictly fresh or naturally ripened food as compared with that of the same food kept for varying periods either in cold storage or at ordinary temperatures, or brought to the consumer through an artificial process of ripening. It may be that in this instance as in many others "our greatest assets will prove to be the things we do not know."

Practically speaking, what we as physicians need to do in formulating diets for our patients is to guide the individual along sane lines of thought not only as to food values but as to the advantage of procuring foods as fresh or as naturally matured as possible and of serving them as best befits the individual, for it may still be true that "what is one man's food may be another's poison."

MAURICE B. BONTA, M.D., Los Angeles.

ANAPHYLAXIS AND ANESTHESIA

To the Editor — It has come to my attention that an answer to a question on the effect of a general anesthetic on anaphylactic shock appearing in *THE JOURNAL*, Oct. 1, 1932, page 1194, has been referred to in medical teaching as implying "that a general anesthetic is likely to prevent or at least delay anaphylactic shock, if, during anesthesia, foreign protein is injected in a sensitized patient." Although this answer includes the caution that its apparently favorable effect should not be allowed to displace other precautionary measures, nevertheless I believe it goes too far when it implies that general anesthesia is of any aid. The literature on anaphylaxis is generally opposed to such a view. The apparent origin of the opinion that anesthesia would prevent or alleviate anaphylactic shock was Besredka's report that ether narcosis would prevent anaphylactic shock in guinea-pigs. This was not confirmed by Anderson and Rosenau in their early work and has failed of confirmation by other workers. Bally (*J Immunol* 17:223 [Sept.] 1929) has shown that ether anesthesia does not deter anaphylactic shock in the rabbit. Krafka, McCrea and Vogt (*J Physiol* 68:292 [Nov.] 1929) have obtained anaphylactic shock in cats under anesthesia. The great majority of the work on anaphylaxis in the dog has been done under anesthesia of various kinds. The nature of the anesthetic used has not been mentioned in many instances apparently because of the writer's conviction that it was generally known that anesthesia would not vitiate the results. Weil, however (*J Immunol* 2:525 [Oct.] 1917), saw fit to comment as follows: "Parenthetically it should be added that ether anesthesia does not in the least inhibit acute anaphylactic shock with death in dogs." Manning and his collaborators in numerous papers, Simonds, Voegtlin and Bernheim, Heymans and many others have reported work in which various anesthetics were used without preventing shock. In the dog, my associates and I have used ether, chloroform, paraldehyde, barbital and vinethene, with and without morphine, and often in combination, without any apparent ameliorating effect. To be sure, vomiting is prevented in the dog by anesthesia and perhaps the bronchial constriction in the guinea-pig may be somewhat less intense, but there is no substantial evidence that if sensitization is high the fatal issue has been either postponed or prevented. I know of no adequately controlled observations in man that warrant a conclusion of any sort. However the experiments on laboratory animals but partially referred to here, together with the evidence that anaphylactic shock is largely a histamine intoxication (Gebauer-Fuelnegg and Dragstedt, *Am J Physiol* 102:520 [Nov.] 1932) and that ether anesthesia (Dale, *Brit J Exper Path* 1:103 [April] 1920) increases the susceptibility to histamine not only lend no support to the idea that anesthesia would diminish anaphylactic shock but actually indicate the reverse.

OPTIMUM AIR CONDITIONS

To the Editor—A man aged 55 who has an old fibrous tuberculosis of the left lung now inactive has had his office air conditioned. What is the optimum humidity for him? What the temperature in relation ship to the outside air? W P ANAMSON MD Tampa Fla

ANSWER.—The human body functions best in a temperature of from 68 to 70 F with a relative humidity of from 40 to 50 per cent. However, the factor of safety is such that no great harm comes from somewhat higher or lower temperatures and corresponding changes in humidity.

There is no good evidence to prove that humidity has any significant influence on old fibrous tuberculosis. At one time it was believed that the rales indicating moisture, which one often elicits over an area of progressive tuberculosis, could be influenced by reducing the humidity of the air. More logical thinking, however, convinces one that the moisture elicited over the area of disease is produced in and about the pathologic process rather than by the outside air that one inhales. A tuberculous process is often spoken of as becoming dry. By this it is meant that less evidence of moisture is elicited on physical examination and that there is decrease in expectoration. If the tuberculosis is of the chronic type, there is evidence of fibrous tissue deposits. Here again the deposition of fibrous tissue is not dependent on presence or absence of moisture in the air that one inhales but on the proliferation of connective tissue cells. One sees persons who develop clinical tuberculosis while working in places where the air is extremely dry and yet moist rales may be elicited over the lesion. Again, one sees patients whose lesions show marked decrease in moisture and the deposit of much fibrous tissue while they are being treated in very humid air. It appears, therefore, that the air one inhales, so far as its humidity is concerned, has but little to do with the progressiveness or retrogressiveness of the tuberculous process. Therefore, air conditioning is a matter of providing air free from dust contamination with the temperature and relative humidity in which the body not only is most comfortable but also functions best.

In the winter it is customary to heat houses and buildings where people work to approximately 70 degrees, although the outside temperature is freezing or below. This has proved satisfactory. Therefore it is just as logical during the summer months to cool the air in buildings to approximately 70 degrees when the outside temperature is high. For a patient with an old fibrous tuberculosis that is inactive, an attempt through air conditioning to keep the temperature of his office at approximately 70 degrees and the relative humidity at 40 to 50 per cent should not only add much to his comfort but also contribute to his health.

RECURRENT SWELLINGS

To the Editor—A man aged 61 has had recurrent swellings of the face, throat, tongue, hands and feet for four years. The swellings almost always come on at 3 o'clock in the morning and apparently involve the tissues deep to the skin although there may be some slight swelling and irritation of the skin but not accompanied by urticaria. The first attack apparently dated from an attack of jaundice which lasted about three months and according to the history was suggestive of catarrhal jaundice. These have recurred every one to three weeks since and swellings as large as a hen's egg are somewhat relieved by epinephrine hypodermically. Investigation has revealed no sensitivity to common foods. The patient's blood calcium is normal and he has had no history of asthma or hay fever and has not been benefited by the administration of calcium. He has also had his teeth removed without benefit. At present I am giving him three-eighths grain (0.025 Gm) of ephedrine at bedtime with the idea of warding off the attacks. What further investigation or treatment would you suggest? Please omit name.

M D Ontario

ANSWER.—The cause of the swellings is problematic. The fact that they occur at 3 o'clock in the morning would indicate that something taken just before bedtime either a food or a drug may be the cause or the patient may be hypersensitive to some article in the bedroom such as a horsehair mattress, a feather pillow, or a camel hair blanket.

It is suggested that, if any of these are present in the bedding they be removed and then if symptoms clear up that they be brought back one at a time to see if the swellings recur.

Drugs are a common cause of swellings especially drugs containing quinine or coal-tar derivatives such as acetosalicylic acid, amidopyrine and acetanilid. These are often taken not

only in the form mentioned but also frequently combined in proprietary and 'patent' medicines. There are many cases of idiosyncrasies to certain sleeping medicines, such as barbitol preparations some of these contain coal-tar derivatives and barbitol. Occasional cases have also been reported from the use of ephedrine, even though ephedrine is used with the idea of combating attacks.

It is suggested also that a food diary be kept, especially of the evening and night meals, and that the foods which are commonly eaten at those times be omitted one at a time for a period of about one week to see what effect will follow, if any.

If skin tests were completely carried out, they need not be repeated, but, if the tests were incompletely done, information may be obtained by such methods in many cases.

MEDLAR'S RATIO FOR LEUKOCYTES IN TUBERCULOSIS

To the Editor—Can you give me any information about Medlar's ratio as mentioned herewith. The leukocyte count affords us a method of obtaining a biopsy so to speak which mirrors the pathological tuberculous process and thus gives valuable prognostic information. In Medlar's interpretation the polymorphonuclear, the lymphocyte and the monocyte are all concerned in the pathological processes at some time during the infection. Some investigators favor the polymorph ratio others the monocyte-lymph ratio. Recently a slide rule has been devised by which Medlar's pathological conception based on the leukocyte count can be expressed in the form of an index. While the Schilling count is of distinct value yet considering the extra time the skill required in differentiating the cells and the possibility of error it is our belief that with the possible exception of the acute tuberculous process it does not give added information that cannot be obtained from Medlar's formula.

G WARD DISBROW MD Summit N J

ANSWER.—Medlar has published in the *American Review of Tuberculosis* (20:312 [Sept.] 1929) a study of the leukocytic reaction in the blood in tuberculosis. He performed weekly total and differential leukocyte counts in 120 cases. In all the charts 5,000 neutrophils, 2,000 lymphocytes and 700 mononuclears were used as the base lines.

The mononuclear leukocyte (the epithelioid cell of the tubercle being the mononuclear leukocyte of the circulation) forms the primary tubercle and takes a large part in the repair of the tuberculous lesion following caseation. The neutrophil is the chief cell in the formation of tuberculous abscesses that leave cavities and ulcers. As long as these continue to enlarge, the neutrophils are increased. The lymphocyte appears in the process as the predominant cell only when the lesion (primary tubercle, caseous lesion or ulcerated lesion) is in the healing stage. The lymphocyte remains in the healing or healed area long after the other leukocytes have ceased to play a part.

From the leukocytic graphs, made from the numbers of each of these three types of cells found in the blood, certain conclusions can be drawn regarding the progress of the disease in each case. The leukocytes respond to the type of damage done to the tissue. In general, the mononuclear leukocyte increase indicates new tubercle formation, the neutrophil tuberculous abscess formation, and the lymphocyte healing of the tuberculous process.

In the majority of cases there is a close agreement between the clinical progress of the case and the leukocytic interpretation. The leukocytes are often the first indication of an exacerbation, even before the appearance of clinical symptoms or x-ray evidence. The majority of tuberculous cases present a stable leukocytic picture. Patients with a septic leukocytic picture are liable to have hemorrhages or exacerbations. Patients with a high lymphocyte, low neutrophil count and only slight mononuclear increase do not have hemorrhages or serious spread with such a leukocyte picture. A lowering of the neutrophils and mononuclears with rise of the lymphocytes, indicates a tendency toward healing.

There are three types of leukocytic formulas indicative of three phases of tuberculosis. These types may shift from one to another with changes in the disease process.

1 In the septic leukocytic picture the total count is usually above normal. The neutrophils are above 65 per cent, usually 70 or more. The lymphocytes are never above 25 per cent and usually below 20. The mononuclears are usually above 8 per cent and may be as low as 5 per cent. This type indicates that the lung process is undergoing abscess formation or extension. Healing is not taking place. A mononuclear count above 9 per cent speaks for new tubercle formation.

2 In the hyperplastic picture the total white count is usually within normal limits, never greatly increased. The mononuclears are above 10 per cent, the neutrophils below 60 per cent, the lymphocytes 25 per cent or more. This indicates new tubercle formation, but without abscesses. With lymphocytes above 30 per cent there is a tendency toward healing.

3 In the nonseptic picture the total count is not over 10,000. The percentage of lymphocytes is high, approaching closely the neutrophil percentage. There may even be more lymphocytes than neutrophils. The mononuclears are below 10 per cent. This picture indicates healing, with no abscess formation and but little indication of new tubercle formation.

Flinn has recently concluded that a high monocytic count, with a normal or low lymphocytic count, suggests an active proliferative lesion. A rising monocyte count suggests an extension or exacerbation of the proliferative process or a complicating extrapulmonary lesion. A high neutrophil percentage suggests an exudative lesion. A rising neutrophil percentage suggests extension or exacerbation of the exudative process. A high lymphocyte count suggests an increased tendency to heal.

The blood picture, therefore, may give valuable aid in determining the kind of changes occurring in the tissues. The leukocytic reaction often agrees closely with the clinical status at the time the blood is taken. Blood counts at frequent intervals are of real value in determining the trend of a case of tuberculosis. The blood picture may reveal an extension of a lung lesion before the physical or roentgenographic signs.

HAY FEVER

To the Editor—A boy, aged 10 years, has always been delicate, is growing fast, is about 2 inches over the average height and is about 2 pounds under the average weight. He has always been active and more energetic than most boys of that age. Large adenoids had to be removed at 2 years of age, the tonsils at 3 and the appendix at 6. He had whooping cough at 2 years, measles at 5 and chickenpox at 8. When he was 4 years old he was exposed to poliomyelitis and was given one dose of antipoliomyelitis serum. Within half an hour he was covered from the top of his head to the soles of his feet with an urticaria. There was absence of vomiting or other symptoms. This condition lasted ten days and was controlled with maximum doses of epinephrine and ephedrine with atropine. Last January a slight attack of influenza lasted three days but following that there was a slight elevation of temperature, less than 1 degree during some part of the afternoon lasting two months during which time he was kept strictly at rest. Nothing could be found in the lungs, sinuses, teeth, abdomen or ears to account for it. Roentgen examination of the chest and abdomen proved to be negative, as also were four tuberculin tests with old and new tuberculin. About three weeks before this was written some congestion of the eyes and nose developed which tended to clear up and was made much worse one day when he picked a few dandelions. This was very suggestive and skin tests were made. It was found that he was sensitive to a great many of the foods including milk, eggs and cereals and to almost all the pollens usual for this district, including dandelions which was very marked. No nasal tests have been made but all the blood counts have been practically normal. The kidneys have always been normal, except that at 5 years he had a slight pyelitis but frequent examination since then has never shown any pus cells or abnormality. At the present time the only symptom is some congestion of the turbinates with some obstruction of breathing, especially during the night. I would appreciate knowing if there is anything that can be done for this generalized allergy to both foods and pollens. No foci of infection have been found anywhere in repeated examinations. Please omit name and address.

M D Canada

ANSWER—The fact that congestion of the eyes and nose occurred about three weeks before the query was written coincides with the beginning of hay fever due to grass pollen. If this is correct, and the positive skin tests would seem to confirm this, the symptoms will continue until the grass pollen season is at an end, somewhere about the first of August.

If, in addition, the boy is hypersensitive to ragweed, the hay fever will start up again about the middle of August and carry on until the first frost.

The picking of the dandelions and the positive skin test to dandelions signifies little, as dandelion pollen is carried little by the wind and therefore is not important as a cause of hay fever.

The child should receive coseasonal injections, small doses, intracutaneously, at this time of dilute grass pollen extract, e.g., 1:10,000. The first dose might well be 0.1 cc. and this dose should be repeated every day or every other day for a week or two and then gradually increased until August 1. This procedure might clear up the condition promptly. All foods that gave positive skin tests should also be thoroughly eliminated from the diet, at least during the hay fever season, and if they cause symptoms at other times of the year they should also be avoided. However, before it is concluded that the boy is clinically sensitive to these foods, such as milk, eggs and cereals, he should be tested out at some future time outside of the pollen season by removing the foods and then prescribing them to see whether symptoms result.

Clinical sensitivity and positive skin tests are not synonymous by any means. Many patients have given positive skin tests to certain foods but may eat these foods with impunity. On

the other hand, many individuals with negative skin tests cannot tolerate certain foods. In other words, every positive skin test, either to proteins or to pollens, must be corroborated clinically before definite conclusions can be reached.

In addition, the fact that the boy gave a reaction to serum suggests extreme caution in receiving any further doses of any kind of serum if this should be necessary at some time in the future. Such serum should be administered very slowly and in many divided doses.

PAROXYSMAL TACHYCARDIA

To the Editor—A man, aged 51, an oil well driller, with an irrelevant past medical history, has had typical attacks of paroxysmal tachycardia since he was 20 years of age. Until the last three years the attacks were mild and infrequent, occurring about once a year and lasting from a few minutes to two or three hours. During the last three years the attacks have occurred on an average of once in two months and last from fifteen to thirty hours. During the last three attacks, alarming symptoms of acute circulatory failure, i.e., marked venous congestion, orthopnea, marked cardiac distress, cyanosis and a feeble uncountable pulse with a heart rate around 250 a minute have developed near the end of the attacks. He complains of agonizing precordial pain, when the attack suddenly ceases. Between the attacks the patient has no symptoms referable to the cardiovascular system, no evidences of cardiac disease are demonstrable by ordinary clinical means and the patient enjoys robust health. In the recent attacks none of the ordinary means of vagus stimulation have had any influence on the condition. Choline chloride was tried once without any effect. Can you suggest any treatment that might be useful in terminating these attacks? Would continuous administration of quinine be indicated in hope of preventing the condition? Kindly omit name.

M D, Wyoming

ANSWER—A heart that can stand the stress of the rapid rate of an auricular paroxysmal tachycardia at the age of 20 cannot do so as readily at 51. At that age there are usually changes of some degree in the coronary arteries and in the heart muscle and the conducting tissues, which make such a rapid rate a more serious matter. A rate of 250, however, is too rapid a rate to maintain an adequate circulation at any time, and attacks lasting from fifteen to thirty hours, even with a slower rate, usually show evidence of circulatory failure.

If it is possible to obtain an electrocardiogram during an attack, it would be interesting to see what it would show. The same case that showed a typical tracing in early life may show aberrant ventricular complexes during the attack in later years, with bundle branch block or even a condition resembling a ventricular tachycardia. Attacks of auricular fibrillation may be interspersed with attacks of paroxysmal tachycardia. A rate of 250 is much more rapid than is found in auricular paroxysmal tachycardia, which rarely goes over 200. An auricular flutter, with 1:1 block, should be ruled out. Quinine in daily doses, adequate to prevent the attacks, is indicated. It should be discontinued at once, however, if there are any evidences of untoward results. Morphine may be of use during the attacks or vagus (carotid sinus) stimulation may be more effective after the morphine.

At the end of an attack there is often a slow, irregular pulse with long pauses between the beats, and anginal pain may occur consequent on the decreased coronary flow.

CYST OR GANGLION OF GREAT TOE

To the Editor—A man about 40 years of age came to me about two months ago with a tender swelling on the inside of the left great toe about one fourth inch from the nail. Thinking it was an abscess I incised it, and to my surprise several drops of a jelly like fluid came out. It was light colored and a good deal like the vitreous of the eye. A few days ago he came in again and said that since the previous visit the swelling had recurred several times and each time he had opened it up and the same kind of fluid escaped. I was unable to probe it to any depth so I incised the tumor and curetted the wound. Now after a lapse of ten days it still continues to drain and does not heal. I can find nothing in my books to give me an indication of what it is and have asked other physicians but they say they do not know. Can you tell me what it is and the proper treatment. I would appreciate your help greatly.

A W PATTERSON M.D., Fonda, Iowa

ANSWER—This condition is doubtless a cyst, which is exactly similar to that which frequently develops over the dorsal aspect of the wrist and is commonly known as a ganglion.

Concerning the origin of these cysts there is considerable dispute. By some they are considered extrusions of the synovial membrane of a joint or of the synovial lining of a tendon sheath. By others they are considered a degenerative process arising in the fibrous tissue of the joint capsule or fibrous tissue overlying a bone. The cysts that form alongside the nail of the fingers or toes can often be traced by careful dissection to the region of the distal interphalangeal joint and may arise from this joint.

The proper treatment is careful excision of the entire cyst wall. This excision can be accomplished with the help of an adequate skin incision and of a bloodless field, secured with the help of a blood pressure band or a tourniquet. Unless one can visualize the involved area exactly, it is easy to leave a small portion of the cyst wall behind and have a recurrence of the trouble.

FACIAL FLUSH IN TUBERCULOSIS

To the Editor—Many years ago while on duty in a government hospital for the tuberculous I was impressed with the observation that, when a tuberculous patient flushes, the color in his face appears in streaks or splotches alternating with streaks or splotches of a pallid hue. This streaking of the face has no relation in appearance at least to the familiar hectic flush, nor is it the pallid condition about the lips and nostrils observable in almost any very ill patient. These last named conditions have often been described as has the peculiar facial expression of the tuberculous. Standard textbooks devote pages to this subject, yet the condition of which I speak has never, so far as I have been able to learn, been mentioned in literature. When a person in health flushes, as from exertion, coughing or blushing the increased color in his face is uniform. When such a person turns pale as from shock fright or in a faint the blanching is uniform. Not so with the tuberculous. I have observed this coloring in streaks chiefly in ambulatory patients and have observed it with sufficient frequency to be convinced that it is always present in patients with advanced pulmonary tuberculosis. I am convinced that the condition is an indication of pulmonary disease but I do not know that it is more marked in tuberculosis than in pulmonary impairment due to other causes. To what extent the condition is the result of a vasomotor disturbance, or to what extent it is due to defective aeration I have not been able to determine. The condition may be observed by simply having the patient lower his head for a few moments or by having him cough. He should be under a good light. I am asking that clinicians who see a large number of pulmonary cases look out for and report on this sign, which may or may not prove to be of value in diagnosis.

BENJAMIN K. HAYS Oxford N C

ANSWER—Formerly, it was believed that the hectic flush is due to toxemia. However, it was observed that the flush is often unilateral and always on the side of the diseased lung. When both lungs are diseased, the flush is more marked on the side of the greater activity of the disease. If the condition were due to toxemia, one would expect both sides of the face to be flushed to an equal degree. Therefore this phenomenon has been explained on a reflex basis. When the sensory fibers of the trigeminal nerve are stimulated, dilatation of the vessels occurs in the area which these fibers supply. The irritation produced by disease in the lung results in stimuli which pass over the afferent fibers of the vagus nerve. In the trigeminal nerve there are dilator fibers of cerebral origin. Thus, the impulses carried over the vagus from the area of disease pass reflexly over the trigeminal nerve, to result in dilatation of the blood vessels, giving the hectic flush. Such a flush or burning sensation over other parts of the body, such as the lobe of the ear or even the skin over the chest wall, may be brought about in the same manner but over different nerve paths. Just why the color in a tuberculous patient's face appears in streaks or splotches alternating with streaks or splotches of a pallid hue is difficult to explain. In such a case there probably is some defect in the vasomotor mechanism, possibly due to afferent impulses from the irritated lung, since other reflex disturbances, such as those mentioned, spasticity of muscles, and so on, are also observed. Defective aeration probably could have such an effect only by affecting the vasomotor mechanism. As was mentioned, further observation of a large number of cases will be necessary to determine whether the impairment is always due to tuberculosis or other pulmonary diseases.

BLACK TONGUE AND HALITOSIS

To the Editor—For more than twenty years a patient has had on the posterior part of the tongue a grayish thick covering with a strong foul smell. The patient is now about 40 years old. The reaction of the saliva is slightly acid. With an alkaline mouth wash the patient gets a stomatitis. Weak solutions of boric acid and Burrow's solution burn. Chamomile flower tea a teaspoonful to a glass of water is well tolerated. Internal iodide medication had to be dropped repeatedly as signs of intolerance developed. Brushing the tongue morning and night with a soft toothbrush has been tried with no success as yet. Aside from the described condition the patient has a vasomotor rhinitis. May I ask you for advice as regards the treatment and is there any hope for cure of this condition? Kindly omit name and address.

M D New Jersey

ANSWER.—Bad odor of the breath associated with either coating of the tongue or a hypertrophy of the papillae just in front of the circumvallate papillae and in the median line is not a rare condition. Apparently the odor is generated by a growth of fungi about the base of the elongated papillae or beneath the coating. The condition described may be a variety of the clinical entity known as black tongue, as the pigmentation

in this defect varies from brownish black to light gray. Foul odors emanating from the mouth as well as from the nose occur in such forms of atrophic rhinitis as ozena but not in vasomotor rhinitis. In any event, treatment is indicated only for the purpose of eliminating the bad odor. Usually thorough swabbing of the region with strong hydrogen dioxide followed by irrigation with warm physiologic solution of sodium chloride is effective if repeated a number of times. In stubborn cases a suitable brush with soft bristles may be used, but, because the foul smelling deposits are located at the base of the papillae, patience and persistence are required. In obstinate cases of black tongue, Prinz (Diseases of the Mouth and Their Treatment, Philadelphia, Lea & Febiger, 1935, p 436) recommends the use of a 10 to 15 per cent solution of salicylic acid in equal parts of alcohol and glycerin, applied on a swab and followed by irrigation with salt solution. The use of scrapers or other methods of mechanical removal has been advocated, but, as Prinz warns, such treatment is likely to promote recurrence.

URTICARIA DURING MENSTRUATION

To the Editor—A married woman aged 30 gives a negative history as to illness other than having had an operation for anchoring the uterus about two years ago. She has been married for five years and has had three abortions one being followed with a tubal infection which required a month's treatment to clear it up. A few months later she noticed that around her menstrual period there were several fair sized swellings below the knees to the ankles. These swellings are painful when they develop and are at first red and after about three days become bluish. After the operation she did not notice them for several months but she has had them again for the past several periods now they develop all along the inner side of the left thigh although formerly both legs were affected. The bluish discoloration did not entirely disappear the last time and there is still some tenderness where the swellings were and an area about the size of a half dollar at each site. Her last period was about two weeks ago and she expects the same condition at the next period. There is no swelling of the feet or ankles and when a tourniquet is used at the top of the thigh the areas do not swell as a varicose vein does although she states that in the morning when she is first out of bed the swellings are smaller and increase in size during the day. One physician told her that they were due to allergy and dieted her without results and another one told her they were due to the condition of her uterus and that after an operation she would be cured. She was relieved for a few months but has had this condition again for several months. I cannot find any mass in the pelvis but there is some tenderness about the left side of the uterus which is larger than normal and down lower in the pelvis than normal. I expect to see her again when these swellings develop and wish you would give me your opinion as to what is the cause of this trouble. It seems that they may be due to an old phlebitis which developed a month or two after a salpingitis, but I cannot make the veins distend so that I can be certain about it and the location of the swellings is not exactly along the course of the veins as they are scattered about the surface of the thigh. The patient states that when they are swollen they are rather hard and they will pit on pressure. The urine is normal. Kindly omit name and address.

M D Minnesota

ANSWER.—The lesions described sound like either erythema multiforme or giant urticaria.

If, as suggested, there is a definite relationship between menstruation and the appearance of the nodules, erythema multiforme is unlikely.

Recurrent attacks of urticaria sometimes accompany menstruation, notably in patients with pelvic disorders. In the majority of such cases, disturbances of the alimentary tract are present also and the recurrence of the nodular swellings may be prevented by careful attention to diet and to elimination.

EXERCISE TOLERANCE TESTS

To the Editor—Please state the significance of the exercise tolerance test from an insurance standpoint in regard to the pulse rate and blood pressure not increasing after exercise or increasing to an excessive degree.

M D South Carolina

ANSWER.—Life insurance companies, although they have been greatly interested in the development of tests of circulatory efficiency that are significant from the standpoint of prognosis, have been unable as yet to arrive at any test or group of tests of definite value in this field. In fact, many medical directors are becoming dubious about ever being able to do so.

In general the pulse rate and the blood pressure are expected to increase after exercise. Failure of the blood pressure to do so may indicate a poor cardiovascular reaction or a very stable vasomotor system while little or no increase in the pulse rate is considered a favorable reaction. It is assumed also that the pulse rate should return to the preexercise rate within two minutes after the prescribed exercise. If it does not do so, further study of the circulatory condition is indicated, but the finding in itself warrants no definite unfavorable conclusion.

In other words, the reaction to exercise is just one of the many points to be considered in arriving at an estimation of the condition of the cardiovascular system.

PERSISTENT FURUNCULOSIS

To the Editor—A man, aged 51, has suffered from multiple furunculosis involving any portion of the body for eighteen years. He is a foreman in a paper and rag warehouse but does little or no hard work himself. While it may seem at first that the dusty atmosphere may be an etiologic factor in his condition may I remark that he has had boils even when away to the country and when at home away from work for a period of a month. He has been treated with regard to hygienic measures such as daily bathing with bland soaps and daily change of underclothing and attention to bowel regulation. He has had all the vitamins in high dosage also calcium compounds in high dosage liver and iron. He uses a sun ray lamp at home which I ordered and have graduated the dosage slowly and progressively for full body exposures. He has had numerous parenteral treatments with vaccines both stock and autogenous nonspecific therapy staphylococcus toxoid, and bacteriophage made from culturing his own pus from the furuncles. (The organism incidentally has always been *Staphylococcus aureus*.) He has had large doses of tin oxide tablets and sulphur by mouth. Diet has likewise been to no avail. The boils have varied greatly in size the largest are about 9 cm in diameter. The patient weighs 201 pounds (91 kg) and is 5 feet 9 inches (175 cm) tall. Physical examination is negative. The blood count is normal as is the blood chemistry including sugar urea and creatinine. Frequent urinalysis is negative. He takes no medication such as might cause or favor skin eruptions. The blood Wassermann reaction is negative. I know of nothing further that I can do for this man. Have you any suggestion as to etiology and therapy? Please omit name.

M D New York

ANSWER—Persistent furunculosis lasting over eighteen years is rather unusual. After a series of furuncles there is usually a rise in the body immunity, which effectively overcomes the infection and protects the individual.

In this instance an effort must be made to raise the skin resistance, as metastatic infection in other tissues has not developed.

It seems that most of the well known remedies and some very doubtful remedies as well have been tried except the use of the x-rays. Several authors report the beneficial effects of roentgen treatment. It has proved helpful in aborting furuncles, in hastening their healing and in stimulating resistance to protect against infection.

It should be used in conjunction with surgery in the larger furuncles but may prove more valuable here as a preventive of further infection. The exposure should be made under the supervision of a competent roentgenologist.

The intracutaneous method of administration of vaccine or toxoid is believed to be superior to the subcutaneous route through stimulating the immunizing bodies in some specific manner. This should be tried at least in resistant cases.

The actual details of personal hygiene should be outlined and checked up repeatedly. Since furunculosis is the result of skin infection, some method of staphylococcus destruction by antiseptics should have some value here, in addition to cleanliness and avoidance of irritation or friction by clothing.

It may be of value to apply an ointment to the skin with or without an antiseptic after bathing.

Regardless of the normal blood sugar, the carbohydrates and sugars should be reduced to a minimum.

PROSTATITIS AND ASSOCIATED SYMPTOMS

To the Editor—A white man aged 40 had a prostatic abscess of idiopathic origin five years ago which ruptured spontaneously and drained through the urethra. He had vague discomfort in the perineum following this which at times became a heavy ache which radiated into the right leg. He had only a few massages of the prostate at the time. During the past year and a half the patient has had migraine-like attacks with typical aura scintillating photophobia increase of nervousness dull boring headache sometimes bilateral and finally nausea. These attacks have varied greatly in frequency and severity. When more frequent they are less severe. The worst ones ended by vomiting. About one year ago he had two very light prostatic massages on different days each of which was followed by atypical attacks of migraine within two hours. The prostatic secretion was essentially normal under the microscope. Since then no massages have been given. The attacks continue and at times incapacitate the patient for twenty-four hours. Is it probable that these attacks are caused by the prostatitis? What method of treatment would you advise in such a case? Are vaccines valuable? Is there any form of heat to the gland worth while? Kindly omit name.

M D Indiana

ANSWER—In rare instances nervousness, headaches and dizziness may be due to chronic infections in the prostate gland, so that this symptom complex may be due to a chronic prostatitis although this is exceedingly rare. On the other hand, the fact that the patient does not have pus in the prostatic strippings when examined with the microscope would lead one to believe that the prostate is normal and hence not a factor. On the other hand the fact that light prostatic massage produces these atypical attacks of migraine must necessarily cause one to stop, look and listen. Because of this occurrence, further investiga-

tion of the prostate is indicated, that is, the prostate should be massaged at weekly intervals and the strippings examined with the microscope. If the strippings show no pus, obviously there is no infection of the prostate that can be drawn into the picture. Without this, the natural impression would be that the attacks of migraine following massage are purely accidental. If there is no pus in the prostate, no treatment would seem to be called for. If, however, repeated examinations of the strippings show pus, heat by rectum and massage should be employed. Whether or not vaccines are indicated will depend entirely on whether cultures from the strippings show infection.

SPONTANEOUS IDIOPATHIC PNEUMOTHORAX

To the Editor—A man, aged 30 worked at the chloreal thermometer trade for some eleven years. During this time he did much glass blowing in molding the bulbs for thermometers. Before starting his day's work on this particular date he was suddenly seized with a severe pain, referred to the abdomen. The diagnosis was finally collapse of the right lung. The day before the lung collapse he stated that he was blowing through much finer tubes than usual and that extra effort was required. However he does not recall any particular time when he felt any sensation other than that due to slightly increased effort. Was the lung collapse caused directly or indirectly by his occupation? Was the collapse aggravated by his occupation? His previous health was excellent. Please omit name.

M D New York

ANSWER—Pulmonary emphysema is a frequent occupational disease lesion in work people who are required to practice deep and forceful inspiration and expiration. In glass blowers and players of wind instruments, among other trades people, through slow changes in the lung tissues, the lungs lose their normal elasticity and the alveoli become distended so that the occurrence of a spontaneous pneumothorax is favored.

The etiology of spontaneous idiopathic pneumothorax is still uncertain. It may occur without any immediate obvious cause or may arise in the course of more or less violent effort in a patient up to then apparently well. About 16 per cent of all cases arise as a sequel to well characterized emphysema. In the absence of known diseases it is quite reasonable to suspect glass blowing to have been a factor in the causation of this spontaneous pneumothorax. A number of actual cases are on record, appearing, however, for the most part in foreign publications.

SIMULTANEOUS DIPHTHERIA AND SCARLET FEVER

To the Editor—I should like very much to know what the possibilities are of diphtheria and scarlet fever occurring in one patient at the same time. Have these two diseases occurred in one person and what is the relative frequency? Please omit name.

M D Iowa

ANSWER—Diphtheria and scarlet fever may occur in the same patient at the same time. It is not uncommon that both diseases are present in patients admitted to hospitals for acute infectious diseases. Of 1,039 patients with scarlet fever admitted to the Edinburgh City Hospital twenty, or nearly 2 per cent, had concurrent diphtheria (Ker. *Infectious Diseases*, 1909). Of 14,025 patients with acute infectious diseases, mostly children, admitted to the Durand Hospital from 1913 to 1933, eighty had scarlet fever and diphtheria on admission (Weaver, G. H. *Medical Report of the Durand Hospital of the John McCormick Institute for Infectious Diseases for Twenty Years 1913-1933*). In this group of cases it would be difficult and in many cases impossible to decide whether the infections developed at the same time or one after the other. Diphtheria may develop as a secondary infection in scarlet fever and vice versa.

TEMPERATURE OF FLUID FOR PHEBOCLYSIS

To the Editor—I am about to write a paper on the problem of maintaining a uniform temperature in infusions. I would appreciate any information you can send me concerning medical opinion as to the proper temperature the method of regulating and the results with the method now in use.

SISTER M CARMELITA R N Convent Station N J

ANSWER—With the modern drop by drop method of phlebotomy, the matter of temperature of the fluid to be injected is generally considered relatively unimportant. It is certainly much less important than is slowness of infusion. It is never

theless of possible advantage to introduce hot fluid, even up to the point of 110 F, if the patient's temperature is subnormal. To maintain such temperature safely at the point of delivery, Paul Titus (A Combined Needle Adapter and Thermometer for Intravenous Infusions, THE JOURNAL, May 19, 1934, p 1676) has devised a needle adapter and thermometer. In general the practice of maintaining the temperature in the container at 120 F ensures delivery into the vein at a temperature of not less than 100 F. If the patient has a high temperature, the solution in the container may be at room temperature.

DERMATITIS FROM ENAMELS

To the Editor—I should like to know whether you have any information regarding what chemicals are present in Cook's Baking Enamel that would produce a very severe dermatitis. I have a patient who has worked in the enameling department of a large corporation for the last eleven years without any trouble. The firm changed the kind of enamel it was using and in three or four days the patient had a severe dermatitis of the arms and feet. Any information you can give me regarding this will be appreciated. HENRY F. HYNEMAN M.D. Wichita Kan.

ANSWER.—The number of possible combinations of the many constituents in Cook's baking enamels aggregates a thousand. This does not mean that a thousand dissimilar chemicals enter these products but instead that the twenty-five or more constituents through quantitative variation may lead to a thousand different formulas. Among other constituents are toluene, xylene, petroleum distillates, (rarely) turpentine glycerin, phthalic anhydride, butyl acetate and butyl alcohol. Almost any of these ingredients might lead to a dermatitis, particularly in persons with increased susceptibility to the action of chemical irritants. It is not possible to advise in this instance that a change be made to any particular type of enamels, since all contain similar ingredients and all are likely to lead to at least an occasional case of dermatitis.

INDICATIONS FOR CESAREAN OPERATION

To the Editor—A primipara aged 28 has the following external pelvic measurements: interspinous 20 cm, intercrural 27 cm, conjugate 17 cm. She does not show anything else abnormal. I have not as yet made a definite attempt to make internal measurements. Would you try to let this woman deliver at term or would you do a cesarean operation? Please omit name. M.D. Texas

ANSWER.—The external measurements have but little value in determining the size of the pelvis, although a diagonal conjugate of 17 cm. would indicate some contraction in the anteroposterior diameter, but one is not justified in performing a cesarean section on external measurements alone, even if they are small. Nature will terminate 75 per cent of cases of contracted pelvis unaided or helped by a simple low forceps operation.

This patient should have a careful, competent internal pelvic mensuration and, unless a high degree of pelvic contraction is discovered, she should be given a good conscientious test of labor. Entirely too many cesarean sections are being done on the basis of the slimmest indications.

POISONING FROM OLEANDER AND YUCCA PLANTS

To the Editor—Will you kindly inform me whether the oleander or yucca plants of Florida can cause a dermatitis which is similar to that produced by ivy poisoning in the North?

EDWARD J. KEMPF M.D. EUSTIS Fla.

ANSWER.—No reports have been found of a dermatitis simulating 'ivy poisoning in the North, produced by the oleander or yucca plants of Florida. The yucca plant is apparently nontoxic. The oleander shrub has been reported as producing poisoning in children and adults. In the case of the oleander, a milky juice exudes from the leaves when punctured, and this juice has poisonous properties.

TYPHOID VACCINATION AND ENCEPHALITIS

To the Editor—Please give me an opinion as to the advisability of revaccination with vaccinia and triple typhoid of a patient with epidemic (lethargic) encephalitis of the Parkinson type ten years arrested in good general condition except for frequent ocular spasms. He is planning a sea voyage through the Canal Zone and way points.

DELL T. LUNDQUIST M.D. Palo Alto Calif.

ANSWER.—There is no apparent good reason why the patient should not receive the vaccines mentioned.

Medical Examinations and Licensure

COMING EXAMINATIONS

AMERICAN BOARD OF OPHTHALMOLOGY. The Cincinnati examination previously announced will not be held. The next examination will be given in St. Louis Nov. 18. Application must be filed before Sept. 15. Sec. Dr. William H. Wilder, 122 S. Michigan Ave., Chicago.

AMERICAN BOARD OF OTOLARYNGOLOGY. Cincinnati Sept. 14. Sec., Dr. W. P. Wherry, 1500 Medical Arts Bldg. Omaha.

AMERICAN BOARD OF PEDIATRICS. Seattle Aug. 8. Philadelphia Oct. 10 and St. Louis Nov. 10. Sec., Dr. C. A. Aldrich, 723 Elm St. Winnetka Ill.

AMERICAN BOARD OF RADIOLOGY. Detroit Dec. 12. Sec. Dr. Byrl R. Kirklin, Mayo Clinic, Rochester, Minn.

NATIONAL BOARD OF MEDICAL EXAMINERS. The examination will be held in all centers where there are Class A medical schools and five or more candidates desiring to take the examination Sept. 16-18. Ex. Sec. Mr. Everett S. Elwood, 225 S. 15th St. Philadelphia.

NEVADA. Reno Aug. 5. Sec. Dr. Edward E. Hamer, Carson City.

NEW HAMPSHIRE. Concord Sept. 12-13. Sec. Board of Registration in Medicine, Dr. Charles Duncan, State House, Concord.

NEW YORK. Albany Buffalo New York and Syracuse Sept. 16-19. Chief Professional Examinations Bureau, Mr. Herbert J. Hamilton, 315 Education Bldg. Albany.

OKLAHOMA. Oklahoma City Sept. 10-11. Sec. Dr. James D. Osborn, Jr., Frederick.

PUERTO RICO. San Juan Sept. 3. Sec. Dr. O. Costa Mandry, Box 536, San Juan.

Connecticut March Examination

Dr. Thomas P. Murdock, secretary, Connecticut Medical Examining Board, reports the written examination held in Hartford, March 12-13, 1935. The examination covered 9 subjects and included 70 questions. An average of 75 per cent was required to pass. Twenty-one candidates were examined, 17 of whom passed and 4 failed. Eleven physicians were licensed by endorsement. The following schools were represented:

School	PASSED	Year Grad.	Per Cent
Yale University School of Medicine	(1929)	84.9

Hawaii April Examination

Dr. James A. Morgan, secretary, Board of Medical Examiners, reports the written examination held in Honolulu, April 8-11, 1935. The examination covered 10 subjects and included 55 questions. An average of 75 per cent was required to pass. Three candidates were examined, one of whom passed and 2 failed. The following schools were represented:

School	PASSED	Year Grad.	Per Cent
University of Pennsylvania School of Medicine	(1932)		83

School	FAILED	Year Grad.	Per Cent
Chicago Medical School	(1920)		75 *
Loyola University School of Medicine	(1934)		74

* Failed in three subjects.

Book Notices

A Manual of Obstetrical and Gynecological Pathology By John H. Teacher M.D. Edited by Alice J. Marshall M.B. Cloth Price \$15.25 Pp 407 with 320 illustrations New York & London Oxford University Press 1935

This contribution to the specialty of obstetrics and gynecology was planned and outlined by Professor Teacher prior to his death. He had also prepared nine chapters for the work, which chapters have been edited carefully by Alice J. Marshall, who had been previously a co-worker with Professor Teacher. The author acknowledges a considerable debt to Professor Frankl, whose work on gynecologic pathology influenced him considerably. The editor has carefully scrutinized and revised the original chapters of Professor Teacher and accumulated new material from relevant notes and papers that were placed at her disposal by Mrs. Teacher. The illustrations have been carefully selected, and most of them represent microscopic changes. A considerable portion of the volume is devoted to a consideration of histology and embryology in relation to cyclic changes and other physiologic alterations associated with menstruation, ovulation and early and late gestation. Aside from the pathology of the placenta and the membranes, little attention is given to pathologic changes relative to the fetus. Various other authorities have contributed to this careful work. A consideration of the bacteriology of the genital tract has been presented by Robert Cruickshank. The author has included a short chapter on technique. This pertains particularly to the collection and primary preservation of tissues and should be of help as a guide to the surgeon in securing and transmitting tissues in their proper manner to the laboratory for microscopic examination. Teacher was so well qualified on account of his studies that the chapters pertaining to cyclic changes, pathology of the endometrium and the implantation and early development of the ovum, together with consideration of early abortions, are in themselves almost classic. One cannot give detailed consideration to the various other chapters in the book but, on the whole, one has a feeling that less attention is given to a consideration of the gross pathology than to the microscopic. The volume would therefore be of much greater value to those who are interested in the microscopic appearance of genital lesions. It constitutes an excellent work on the histopathology of the female generative tract and is well worthy of careful scrutiny. It would, of course, be impossible to include within the pages of the volume all the gross and microscopic pathology of the female generative tract. The authors have concentrated and succeeded in making a definite contribution to current literature.

Traité de gastroscopie et de pathologie endoscopique de l'estomac. Par François Moutier, chef de laboratoire de la Faculté de médecine. Préface du Professeur P. Duval. Travail de la clinique de thérapeutique chirurgicale de la Faculté de Paris (Professeur Plerro Duval). Paper Price 120 francs. Pp 347 with 113 illustrations. Paris: Masson & Co 1935

This excellent work constitutes the first atlas of gastroscopy since Schindler's atlas appeared in 1923. Duval has written the preface, in which he calls special attention to the fact that gastroscopy has now become an indispensable clinical method. Moutier, whose many papers on gastroscopic problems are well known, follows closely in the technical part the statements of the German authors and gives a precise description of the modern flexible gastroscope and its use. He underlines the sentence that danger in gastroscopy is only of historical importance in that it existed for the rigid instruments but not with the modern flexible gastroscope. An exact description of the normal gastric mucous membrane is given. It is important to note that Moutier does not hesitate to enumerate the various possibilities for being mistaken and for considering as pathologic formations that are quite normal. In a method such as gastroscopy, in which the subjective factor is large, such mistakes are always possible and must be avoided. These chapters on the normal gastric membrane show the great advance in our knowledge of the gross anatomy of the stomach resulting from the use of the gastroscope. In the sections dealing with pathologic alterations, Moutier describes carefully and critically the great variety of pictures that are well known

to every gastroscopist. In an important chapter on chronic gastritis Moutier goes his own way, subdividing this disease on a purely anatomic basis. The chapter on syphilis is of special value, because no similar observations exist in the gastroscopic literature. The sections on the benign gastric ulcer and tumors are lengthy and well written. In the chapter on the postoperative stomach Moutier confirms the observations of earlier authors, all of whom noted the frequency of an extremely severe chronic gastritis. He shows such pictures as well as several jejunal ulcers. This book will doubtless have a profound influence in aiding the introduction of gastroscopy as a safe routine clinical method and in affecting the conceptions of gastric disease in French speaking countries, as the German gastroscopists did in German speaking countries many years ago.

Aids to Embryology By Richard H. Hunter M.D. M.Ch. Ph.D., Lecturer in Anatomy Queen's University Belfast. Second edition. Cloth. Price \$1.25 1 p 172, with 39 illustrations. Baltimore: William Wood & Company 1934

The chief object of this little book and others in the same series is to provide a summary of the facts needed by medical students in order to pass the examinations set in Great Britain. It should be useful to others who wish to review the subject for similar purposes. There have been some additions and considerable revision of the first edition. The subject is presented only so far as it helps in the understanding of adult relations and of abnormalities in development. The chief problems of general embryology are outlined (twinning is omitted, however) and the development of the fetal membranes and of the various systems of organs in man are described. Considering the small amount of space available, the author has succeeded admirably with the help of a series of clear simple diagrams. Under the circumstances, ambiguities are unavoidable. Thus the definitions of the chorion frondosum and anencephaly give false impressions. Attention should be called to certain faults. The accounts of the menstrual cycle and of the central nervous system are not abreast of present knowledge. All "blue babies" are explained on the basis of the patency of the ductus arteriosus. The statement that true hermaphroditism has not been found in man is incorrect.

Handbuch der Kinderheilkunde. Ein Buch für den praktischen Arzt. Herausgegeben von Geh. Med. Rat Prof. Dr. med. M. v. Pfaundler, Direktor der Kinderklinik in München und Geh. Med. Rat Prof. Dr. med. A. Schlossmann, Direktor der Kinderklinik im Düsseldorf. Band X. Die Hautkrankheiten des Kindesalters. Bearbeitet von J. Becker et al. Fourth edition. Paper Price 169 marks. Pp 884 with 383 illustrations. Berlin: F. C. W. Vogel 1935

This work needs no introduction to the medical world. The tenth volume has all the merit of the preceding volumes and not only complements them but also forms an important independent addition to the literature of pediatrics and dermatology. The first edition of the *Handbuch*, which appeared almost thirty years ago, contained a restricted section on skin diseases of childhood. In the preparation of the second edition, four years later, it became apparent that a special volume on skin disorders was necessary, and this was to have been edited by Schlossmann. The World War, the death of Leiner who was to have been the main contributor, the illness of Schlossmann, and other circumstances delayed the appearance of the special volume. After Schlossmann's death in 1932 the preliminary work was taken up again and carried forward under great difficulties. Dermatologists experienced with the dermatoses of children, and pediatricians interested in skin diseases have contributed to the volume. It is thus a product of expert contemporary thought in both pediatrics and dermatology. In accordance with the basic principles on which the "Handbuch" was constructed, the main emphasis is on practical diagnostic and therapeutic questions. The authors consider those dermatoses which occur only in childhood and also those which have special symptoms and characteristics in this period of life, though occurring at all ages. No attempt is made to maintain a strict systematic classification, because this presents many difficulties. In a book of this kind some overlapping in the various articles is unavoidable, but the editors have taken precautions to reduce reduplications and contradictions as far as possible. That certain authors touch on subjects which are

considered more fully by another (Pringle's disease, Schüller-Christian syndrome) is due to differences of opinion as to the origin and nature of these conditions. Attention is called to erythema annulare rheumaticum (Lehndorff-Leiner), page 584, which receives fuller treatment than has heretofore been accorded it. This book is in the same format as the other volumes and is richly illustrated. Attention should be called to the many excellent colored plates, which are of special value in the study of skin diseases. The full table of contents, nine pages long, the marginal outline notes, the clear divisions and subdivisions of the material, and the many bibliographic citations at the end of each chapter make this a handy book to use. As the work is chiefly valuable for reference, a good index is desirable, and the subject index, compiled by Dr Erna Eckstein-Schlossmann, appears to be entirely adequate. However, many will feel keenly the lack of an index of proper names. The book is a noteworthy contribution to the study of skin diseases in childhood. It is one of the most important contributions of the year to the pediatric literature.

The Curriculum in Sports (Physical Education) By Seward C Staley Professor of Physical Education University of Illinois Cloth Price \$2.50 Pp 373 Philadelphia and London W B Saunders Company 1935

This is designed primarily as a textbook for students and teachers of physical education or, as the author prefers to call it, sports education. A considerable portion of the first half of the book is devoted to a philosophical discussion of education and physical education in general, to a review of the history of physical education, and to a defense of the substitution of the term sports education for the conventional physical education. The author argues that physical education in the literal sense is impossible and that consequently the use of the term is unjustified. Gigantic sports events and competitions primarily for the entertainment of the public are condemned as an abuse of the function of the school. In enumerating the objectives of the physical activities program, the author emphasizes mental and social values as well as physical development. The most useful portion of the book is a detailed consideration of the formulation of a curriculum of sports education with suggestions concerning activities, instructional methods, and procedures for measuring accomplishment. As this is distinctly a textbook and not easy reading, it probably will have little interest for the general reader, but it should be distinctly useful to those engaged in this aspect of education.

Sammlung psychiatrischer und neurologischer Einzeldarstellungen Herausgegeben von Prof Dr A. Boettroem und Prof Dr J. Lange Band V Konstitution und Prozesse in der Schizophrenie Von Medizinialrat Dr Skälweit Privatdozent für Psychiatrie und Neurologie an der Universität Rostock. Paper Price 4.50 marks Pp 88 with 6 illustrations. Leipzig Georg Thieme 1934

This volume is a complete analysis of the process of schizophrenia as analyzed by means of the Rorschach test, the observations being correlated at the same time with the body structure types of Kretschmer. The study consists of an analysis of ninety chronic cases and twenty-three acute cases. The chronic cases are tabulated individually, the acute cases are also studied by themselves, and the type of intelligence and the "life type" of each is analyzed. The third part of the research consists in a direct investigation by means of the Rorschach psychogram of the patient's status in different periods of the disorder. In this part the data are tabulated and case histories are presented. Section III is especially interesting for it shows certain factors that have not been indicated by previous investigators as regards the form of the psychosis. The speed of its course and other features of the mental disorder have only been suggested by previous studies but are here gone into more deeply. The report concludes with a ten point summary in which the author attempts to show various differences between the schizoid make up and the manic-depressive make up as well as the nature of the basic defect of the schizophrenic. The work is a contribution to our knowledge of this disorder but is of more value to psychiatric research workers than to psychiatric clinicians for the style is complicated and a knowledge of the basic techniques of Rorschach and of the postulates of Kretschmer is presumed.

Veterinary Helminthology and Entomology The Diseases of Domesticated Animals Caused by Helminth and Arthropod Parasites By H. O. Mönnig B.A. Dr. Phil. B.V.Sc. Professor of Parasitology Faculty of Veterinary Science University of Pretoria Cloth Price \$9 Pp 402 with 264 illustrations. Baltimore William Wood & Company 1934

This was written especially as a textbook for veterinary students, but it lists fifty-seven parasites affecting man. Forms that are relatively unimportant from the veterinary aspect, such as *Necator americanus*, are accorded but little space. Parasites of veterinary significance are discussed briefly as to life cycles, pathogenicity, symptoms, diagnosis, treatment and prophylaxis. A convenient host-parasite list gives all the parasites of each host, together with the page reference. The book is not intended to be a complete and exhaustive treatise on all human and animal parasites. As a ready reference work for the more important forms, it should be of service.

Les encéphalites psychosiques Par L. Marchand médecin chef de l'Asile Clinique (St. Anne) et A. Couriole Préface du Dr E. Toulouse Paper Price 25 francs Pp 144 with 31 illustrations Paris Librairie E. Le François 1935

This is an elaborate and ambitious study of 120 cases, 101 fatal, of acute, subacute and chronic psychosis, without any abnormal neurologic signs or symptoms but with inflammatory and degenerative microscopic alterations in the brain. Of the 101 fatal cases, forty-four were "primary," nineteen arose in the course of a chronic psychosis, sixteen followed the puerperium, twenty followed various infections, and two were postoperative. A state of acute delirium was present in all. Nitrogen retention was such a constant feature that the term "encephalite azotémique" is proposed. It is admitted that this is no clinical entity, that the etiology varies and that predisposition plays an important part, but claim is made for a definite and fairly uniform histologic picture. Although one may take issue with the authors on many points, they must be given credit for originality and great industry. It is a valuable contribution to the study of the vague group of psychoses usually designated in the acute state as "acute delirium," "toxic-infectious psychosis" or "collapse delirium."

Aids to Surgery By Cecil A. Joll M.B. M.D. B.Sc. Senior Surgeon and Lecturer on Surgery to the Royal Free Hospital and Reginald C. B. Ledlie M.B. B.S. F.R.C.S. Surgeon to the Miller General Hospital Sixth edition. Cloth Price \$2.75 Pp 612 with 44 illustrations Baltimore William Wood & Company 1935

This compendium represents one link in a long chain of compact booklets that cover the entire field of medicine and surgery and are especially designed to assist students in grouping and memorizing the subjects on which they are to be examined. The call for a new edition of this handsome volume proves its popularity. The work has been rewritten, enlarged and supplied with illustrations, the first of which is a tribute to American surgery, as it reproduces incisions recommended by Kanavel for the treatment of infections of the hand. The scope of the volume has restricted the authors in the main to a description of essential surgical principles and practice. Nevertheless, owing to an enviable ability to say what they want in a brief and lucid manner, the authors have succeeded in squeezing into their little book an immense amount of information. Not only the student but a general practitioner wishing to brush up his knowledge of surgical conditions will find this small volume inexpensive and extremely handy.

Thirty Second Annual Report 1933-1934 of the Imperial Cancer Research Fund Under the direction of the Royal College of Physicians of London and the Royal College of Surgeons of England. Paper Pp 31 London 1934

The first part of this report gives a concise review of the content of the eleventh scientific report, which was reviewed in THE JOURNAL May 18. The most important new feature of this report is a table listing the strains of transplantable tumors maintained by the Imperial Cancer Research Fund. Twenty-eight strains are listed. The average success of grafting and the effect of reinoculation in positive animals with the same strain and with another are reported for each strain. The importance of the reinoculation behavior is understandable from the fact that it is bound up with the occurrence of spontaneous regression and the behavior of the tumors to changed environment and other conditions of growth. It was formerly

shown by Russell and by Foulds that two distinct mechanisms may be responsible for the progressive growth of transplantable tumor strains. In some strains the parenchyma does not excite a significant degree of resistance. In the majority of progressively growing strains, however, resistance is produced but the parenchyma of the strain is insensitive to it. In such cases the presence of the resistance can be demonstrated by a re inoculation of tumor bearing animals with another sensitive strain.

Medicolegal

Hospitals Rendition of Emergency Treatment Not Acceptance of Patient—The regulations of the defendant hospital forbade the acceptance of patients afflicted with contagious diseases. The plaintiff took his 2½ year old daughter, desperately ill with diphtheria to the hospital. There under direction of the house physician, Dr Stock, the child was carried to the emergency room a swab was made of her throat and oxygen and 20 000 units of antitoxin were administered. A few minutes later 20,000 more units of antitoxin was administered after a consultation between Dr Stock, the hospital superintendent and another physician. Soon thereafter the superintendent ordered the child to be removed from the hospital. Dr Stock advised the plaintiff to obtain a physician immediately and gave him a memorandum of what had been done. The plaintiff then drove with the child about seven miles to his home. About ten minutes later the plaintiff's family physician arrived but the child died within about five minutes thereafter. The plaintiff then sued the hospital. He did not contend that the child's death was caused by failure to receive her in the hospital but that death was accelerated by the negligence of the hospital attendants, in that after receiving her and after rendering proper treatment for a while, they abandoned her when her condition demanded that she remain in bed receive further treatment and be kept where oxygen could be given in case of heart attack. From judgment in favor of the plaintiff, the hospital appealed to the Supreme Court of Alabama.

The defendant hospital, said the Supreme Court of Alabama, was under no duty to accept the child for treatment and may have made itself liable to other patients if it had admitted her. For the plaintiff to recover, the evidence must show that the death of the child resulted from or was accelerated by the failure of the hospital to render some service which it was duty bound to render. The hospital could become duty bound to render service either (1) by undertaking to provide full hospital service or, (2) without undertaking to provide full hospital service, by rendering knowingly emergency treatment which created an extremely dangerous condition unless further partial hospital service was rendered until that hazard voluntarily created by the defendant was passed. The court was of the opinion that the evidence did not justify a finding that the defendant hospital undertook to provide any hospital service except such as may have been rendered reasonably necessary by the treatment that was given. The only fair inference to be drawn from the facts, said the court, is that the treatment given the child was but an emergency treatment. There was no evidence that the hospital undertook to provide full hospital service in violation of its regulations. To uphold the plaintiff's contention, said the court, we must assume that if the hospital did not propose to render hospital service it should have sent the child away in a desperate condition without emergency treatment, when such treatment was available and provided the only hope of recovery. The willingness of the hospital to provide such treatment should not be used to its prejudice.

Could a jury, the court asked, reasonably find that the treatment administered by the defendant accelerated her death and that careful attention at the hospital after it was given would have prolonged her life? What effect on her vitality did the antitoxin produce? The physicians who testified at the trial all agreed that a patient suffering from diphtheria should abstain from any physical exertion, whether or not antitoxin

is administered. But, said the court, this requirement is not violated when the father of a small child takes her in his arms to his home in a car. None of the physicians testified that antitoxin depresses the heart. On the other hand, one physician stated that it does not have that effect. The court could find no evidence that the antitoxin created a condition which was a proximate contributing cause of the immediate death. The judgment of the lower court in favor of the plaintiff was therefore reversed and a new trial ordered.—*Birmingham Baptist Hospital v Circus (Ala.), 157 So 224*

Accident Insurance "Complete Fracture" Defined.—The defendant insurance company promised to pay certain benefits to the plaintiff "upon receipt of satisfactory proofs including an x-ray photograph, indicating the complete fracture of one of the long bones of the arm." Contending that he had suffered a complete fracture of the ulna of the left arm, the plaintiff sued the insurance company. The lower court gave judgment for the insurance company, and the plaintiff appealed to the court of appeal of Louisiana, second circuit.

The question to be determined, said the court of appeal, is whether or not the injury to the ulna of the plaintiff's left arm amounted to a "complete fracture," which has been defined as "a total separation of the boneal alignment of a given bone, one in which the bone is entirely broken across." The roentgenogram of the plaintiff's injured arm, with the findings of a physician consulted by him that the fracture was complete, was sent to the defendant's home office. The roentgenogram, according to two radiologists testifying for the insurance company, revealed an incomplete fracture of the ulna. On behalf of the plaintiff two physicians testified that they believed that the ulna was completely broken across. They stated that by manipulation of the lower arm at the situs of the injury they could hear mild crepitus, which they attributed to the broken ends of the bone grinding together even though they found the fracture not discoverable by simple touch. Medical experts, called by the insurance company, testified that mild crepitus may be produced from an incomplete fracture, hardened tissues ligaments and muscles. Since it was shown that roentgenograms will unquestionably reveal fractures of the bones of the arm with such clearness that experienced roentgenologists may not err in interpreting them, since roentgenologists testified that the fracture was not complete, and since, according to the evidence crepitus may spring from causes and conditions other than a complete fracture, the court concluded that the plaintiff's physicians were mistaken in their diagnosis of the injury to the arm. Accordingly the judgment of the lower court in favor of the insurance company was affirmed.—*Mervether v Columbian Mut Life Ins Co (La) 157 So 156*

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

The Modern Proctologic Clinic M J Synnott New York—p 196

Hepatoptosis—McClure and his associates report a case of hepatoptosis in which the positions and anatomic characters of the various intra-abdominal organs were definitely established by roentgenograms of the untreated abdomen, pyelography, barium gastro intestinal studies and pneumoperitoneum. The exact positions of the spleen and liver were established by contrast roentgenograms after intravenous administration of a colloidal suspension of thorium dioxide. This medium permitted roentgen demonstration of the diminution in the size of the liver and the contained gummatous area resulting from antisyphilitic treatment. Fifty-three uncomplicated cases of hepatoptosis, or total displacement of the liver have been collected from the literature and the described symptomatology has been correlated. The reported results of hepatopevy indicate that the operation is an efficient measure for relieving the symptomatology.

Duodenal Extract as an Adjuvant in Treatment of Peptic Ulcer—The general plan of diet that Rivers used in the treatment of eight cases of benign peptic ulcer was that used by Sippy and his colleagues. Instead of gradually increasing the amount of food taken, however this was increased rapidly so that after four or five days the patients were taking a rather liberal diet such as that usually given patients on ambulatory regimens. Large amounts of alkali were not used. The use of sedatives and belladonna has been continued in the belief that the treatment of ulcer is facilitated. Whenever possible the scrupulous removal of foci of infection is advised. It is not expected that the extract of duodenal mucosa and submucosa will prove to be a specific for peptic ulcer. If some of the protecting mechanisms inherent in duodenal mucosa and submucosa could be assimilated and maintained in an extract made from these tissues such a substance would be invaluable in the treatment of ulcer. It has not been proved whether these desirable qualities are preserved in the extract obtained from

the mucosa and submucosa of the duodenum of hogs used by the author. Furthermore, such substance, when given orally, may be inert, although experimental work now being carried out gives evidence to the contrary.

Allergic Reactions of Actinomycetes—Mathieson and his collaborators state that infection and immunization with acid-fast actinomycetes tend to produce an allergic sensitization in experimental animals. No cross sensitization to tuberculin could be demonstrated. Continued immunization leads to desensitization. Normal persons give more frequent and more marked skin tests to Actinomyces bovis than do actinomycotic patients. Whereas single injections of Actinomyces bovis rarely produce infection repeated inoculations usually do. This is in agreement with the observations of Nakayama, who first suggested that allergic sensitization is a factor in the etiology of actinomycosis. No sensitization demonstrable by skin tests could be induced in rabbits inoculated with saprophytic aerobic actinomycetes. Representative actinomycetes do not elicit reactions similar to those described by Schwartzman for meningococci and other bacteria.

Endocrinology and Behavior Disorders of Children—Lurie points out that in evaluating the power of an endocrine disorder to produce a behavior disorder, both direct and indi-

rect effects must be considered. The direct effects may be obvious and easily recognizable, as, for example, the mental retardation associated with cretinism or the mental deterioration that occurs in adult myxedema. On the other hand, the direct effects may be subtle and affect only the personality make up of the individual. This is often seen in cases of Froehle's dystrophy. The indirect effects are due to the emotional conflicts produced in the child as a result of his attitude to the abnormal physical condition produced by disturbance in the endocrine function. It is essential that these indirect effects be recognized, because they are often responsible for the child's inability to adjust normally to his situation in life. Approximately 20 per cent of the first 1,000 children studied at the Child Guidance Home showed various forms of glandular disturbances. In 93 per cent of these cases there appeared to be a direct causal relationship between the behavior disorder presented by the child and the endocrine disorder. The pituitary was most frequently involved. Mental retardation was most often associated with thyroid disturbances. No definite correlation could be established between the problem presented by the child and the endocrine involvement found to be present. Pituitary dysfunction was frequently present in all the cases of stealing. In a small group of cases, in which the problem was one of speech disturbance, there were extreme motor restlessness and destructiveness. The physical and mental development of these children was normal. All were found to be suffering from hypothyroidism. Seventy-one of the children in the series received glandular therapy. In 33 per cent the results were good, in 50 per cent fair and in 17 per cent poor. Endocrine disturbances cannot all be corrected by glandular therapy. This is especially true of glandular overactivity. Glandular therapy, like all other forms of therapy, to be successful, must be based on correct diagnosis.

Experimental Scurvy—Abercrombie observed that the thyroids of guinea-pigs in scurvy present irregular follicles with higher epithelium, a reduced amount of nonuniformly stained but extensively vacuolated colloid and an increase in the inter-follicular cells. These changes are more marked in chronic scurvy of long duration than in acute scurvy. Potassium iodide, when administered to animals with scurvy, causes a decrease in the number of vacuoles and an increase in the amount of the colloid, accompanied by a flattening of the epithelium and a decrease of the interfollicular cells. Thyroid substance produces similar results, except that the epithelium is not flattened but is returned to the normal medium height. Potassium iodide and thyroid substance, in the doses administered, do not tend to prolong the life of the animal in experimental scurvy. Thus, it appears that vitamin C is not concerned with iodine metabolism.

Basophilic Degeneration of Heart Muscle.—In a study of 320 consecutive postmortem examinations of sections of the heart obtained by routine procedure, Haumeder found the lesion (basophilic degeneration) described by Hewitt in 1907. The areas of degeneration were of microscopic size. It is her impression that the degeneration passes through several phases. With the hematoxylin and eosin stain, the degenerated portions were seen as basophilic patches that generally occupied the centers of the muscle bundles and frequently included the well preserved, often hypertrophied, nucleus. They always were of well defined limits and at the periphery of each was a zone of normal muscle tissue. No tissue reaction could be seen in the degenerated areas. The normal structure was preserved in the immediate neighborhood and even in the continuation of the involved muscle bundle. No gross change in the heart muscle could be observed. In the early stage of the process these degenerated areas stained a rather dark blue and were fairly dense, finely granular and occasionally clumped, and sometimes included fragments of muscle fibers. As the process advanced these areas stained a lighter blue, and what was apparently vacuolization appeared. In advanced stages there was left only a fine network of basophilic, intertwining fibers, which included small tissue spaces, the lesion being rather indistinct. The most frequent single site of the lesion was the septum. Closely following this in frequency was the left ventricle, the right ventricle showed fewer lesions. Of the cases in which the lesion was found in more than one site, those in which the septum and left ventricle were involved were the most numerous. The lesion was found only five times in the right ventricle alone and was found in combination in the right ventricle and septum only twice. In order to ascertain the nature of the lesion, several differentiating stains were used. The lesion was found most frequently in cases of malignancy and heart disease. It was also found in many cases of infection and inflammation, as well as in single cases of electrocution, drowning and toxemia from burns. Staining reactions showed that the areas contained mucin as well as a component related to glycogen.

Other Laboratory Methods in the Handling of Thyroid Disease. G. D. Mahon Jr. Dallas, Texas.—p. 841

Operation on Common Bile Duct—Allen and Wallace incorporate some points of the technic of Cheever and Bakes and certain details advocated by others in the development of a more or less routine management of the operation on the common bile duct, which is given. The indications for exploration of the common bile duct are given. Routine dilation of the papilla of Vater in surgery of the common duct and

temporary external drainage of the duct by catheter are advocated. Some experimental and considerable clinical evidence is presented showing that dilatation of the papilla of Vater can be carried out with safety. It is probable that dilatation of the outlet of the pathologically distended common bile duct may last some time. It would appear that dilatation of the normal papilla in dogs is not permanent.

Suppurative Pericarditis—Bunch believes that the incidence of the disease is much greater than indicated by the less than 200 operative cases reported in the literature. This is borne out by Brooks, who in necropsies done in 200 consecutive cases of pneumonia found seventy-five with positive blood cultures or pathologic signs of septicemia and not one with purulent pericarditis. Nontraumatic suppurative pericarditis is essentially secondary and most frequently follows respiratory disease, particularly pneumonia, septicemia, rheumatic fever and osteomyelitis. The symptoms of pyopericardium are those of sepsis and impaired circulation from mechanical embarrassment of heart action due to increasing pressure made on the heart by the accumulating effusion. When infection of the pericardium occurs, there is apt to be precordial pain with exacerbation of septic symptoms already present. There is more often, however, continuation of symptoms in a patient who is obviously not doing well. There may be chills with high fever. The dyspnea may be extreme. The diagnosis of pyopericardium remains a challenge to the profession, for effective treatment depends on early recognition. Symptoms are only suggestive, but physical signs are characteristic. In spite of the nominal danger of puncturing the heart or of injuring the coronary vessels with the needle, careful paracentesis is indicated in effusion to determine the character of the fluid. Roentgen examination of the chest should always be made. Pericardial effusion is present when there is an enlarged area of precordial dullness shifting with change of position and when roentgen examination shows a water bottle shadow with the base below. The mortality of purulent pericarditis treated medically is practically 100 per cent. Although suppurative pericarditis most often follows pneumonia, there may be other complications of the disease, notably empyema. Winslow and Shipley state that in the 128 cases reviewed by them empyema was diagnosed and drained in sixteen patients, seven of whom recovered and nine died following thoracotomy. The treatment of suppurative pericarditis is adequate dependent drainage by open operation as soon as the diagnosis is made. After pericardiectomy, if septic symptoms continue or return after improvement has begun, an encapsulated pus pocket should be sought for in the posterior pericardium or in the pleura. Left undrained, such a pocket will result in death. After recovery, many patients have normal function of the heart. The author has confirmed this in his two cases by physical and roentgen examination and by electrocardiographic study.

Scalenus Anticus Syndrome—Ochsner and his associates point out that the scalenus anticus syndrome is a clinical entity the symptoms of which are identical with those of cervical rib. The symptoms are the result of compression of the brachial plexus and subclavian artery on the first thoracic rib. This compression may be due to an abnormally low position of the shoulder, high fixation of the sternum and ribs, low origin of the brachial plexus and elevation of the first thoracic rib due to spasm of the scalenus muscles, resulting from brachial plexus irritation. The first three conditions are predisposing, whereas the last is an exciting factor. Irritation and stimulation of the brachial plexus by pressure of the first rib causing spasm and shortening of the scalenus anticus muscle result in elevation of the first rib, thus establishing a vicious circle. Vascular changes are frequently present but are usually missed unless oscillometric studies are made. The scalenus anticus syndrome must be differentiated from the cervical rib syndrome, subacromial bursitis, supraspinatus tendon rupture, cervicodorsal sympathalgia, Raynaud's disease and brachial plexus neuritis. The treatment consists of resection of a portion of the scalenus anticus muscle. Six cases of scalenus anticus syndrome, with successful operation in four, are reported.

Malignant Changes in So-Called Benign Giant Cell Tumor—Coley is still of the opinion that giant cell sarcoma is always benign and never gives rise to metastases. While some

of the cases reported as benign giant cell tumors that later become malignant may be best explained as errors in diagnosis, there is a considerable number in which the evidence indicates that the primary tumor was a true benign giant cell tumor which later, because of some unknown cause, changed in character to a malignant metastasizing tumor. This distinction is really only academic. The proportion of cases in which tumors diagnosed as benign giant cell tumor by experienced pathologists have later become malignant, although small, is actually much larger than has been recognized by recent writers. It is probably in the neighborhood of 15 per cent. The acknowledgment of the fact that a considerable number of giant cell tumors do later become malignant should not lead one to abandon conservative methods of treatment for more radical measures (amputation). It should increase the efforts to arrive at a correct diagnosis at the earliest possible moment. The patient with an apparently cured giant cell tumor should be cautioned to avoid any local trauma. The fact that such a high percentage of the authors' series of malignant giant cell tumors were treated by irradiation (radium or x-rays) after curettage suggests that this mode of treatment should be abandoned. If irradiation is the method of choice, it should be used alone and not in conjunction with curettage. He concludes that surgery (curettage, chemical cauterization, without packing or drainage), with or without postoperative toxin treatment, offers the greatest proportion of permanent cures with the shortest period of disability and the least impairment of function. A brief period of postoperative toxin treatment (from four to six weeks) will lessen the number of recurrences. The fact that such a considerable number of cases diagnosed as benign giant cell tumor have later become malignant leads one to ask whether the use of the term benign giant cell tumor should be continued or whether a return should be made to the older classification of giant cell sarcoma.

Relation of Dust to Tuberculosis—Hawes believes that exposure to protein dusts, some of which may occasionally cause asthma, hay fever or other anaphylactic phenomena, to the carbohydrate dusts such as flour, which presumably have no effect, specific, irritating or otherwise, and to the inorganic non-silicon-containing dusts, including lime, marble, carbon and other elements, in normal amounts and under normal conditions will not reactivate an arrested or quiescent tuberculous process. He does believe, however, that dust in excessive amounts under abnormal conditions, such as street dust in winter and fall or germ laden dust from sleeping cars, which might well cause irritation and infection of throat, trachea and bronchi, is a potential source of harm. Dust that may cause allergic phenomena, such as asthma, asthmatic bronchitis or hay fever, will not reactivate or harm a tuberculous process. As to allowing an arrested or quiescent tuberculous patient to take up a trade in which he would be exposed to a harmless dust, the author would be quite willing to allow his patients to take up such dusty work unless the conditions as to dust were extremely bad.

Nature of Pulmonary Alveolar Lining—Josselyn states that the black lines seen on alveolar septums in silver nitrate impregnations of lungs are explainable otherwise than by the view that characterizes them as outlines of lining epithelial cells. The occasional nuclei seen in alveolar walls in addition to those of the capillary endothelium belong to histiocytes and possibly other connective tissue cells. The phagocytic cells that occur in such profusion in the alveoli in case of need are histiocytes and of largely extraneous origin. The alveolar walls, in addition to the capillary vessels and cells, consist of a membrane composed of reticular and elastic fibers and a homogeneous transparent ground substance. It is on the latter that the continuity of the membrane depends. Alveolar pores are seen sparsely in young adult lungs fixed while inflated with air. They are more frequent in older animals and in those whose lungs were fixed by the intratracheal introduction of fluid. They thus appear to owe their existence to the traumas of everyday life as well as to those of fixation.

Subtotal Pancreatectomy for Hyperinsulinism—In McCaughan's experience the following technic has simplified subtotal pancreatectomy. Shortly before operation the patient is given 500 cc of a 10 per cent solution of dextrose intravenously, and the stomach is thoroughly emptied of fluid and gas by aspiration. The preliminary medication consists of one-sixth grain (0.01 Gm) of morphine sulphate and $\frac{1}{150}$ grain (0.0004 Gm) of atropine sulphate given hypodermically. Ether anesthesia is used by preference because of its effect in sustaining and even elevating the normal level of the blood sugar. A long left midrectus incision is made. The gastrocolic omentum is divided transversely and a gauze pack is placed against the stomach, which is rotated slightly and drawn upward by an assistant. A second pack is placed over the transverse colon, which is then displaced downward. The small of the back is elevated by means of the operating table backrest. The resection is begun by dividing the peritoneal investment along the lower margin of the pancreas and grasping the tail with

a suitable forceps and drawing it slightly forward and downward. Temporary tape ligatures are passed about the splenic vein and splenic artery. The subsequent dissection is directed toward the freeing of the tail and the body of the pancreas from the splenic artery and vein, because it not only enables one by traction and countertraction to display the numerous tributary vessels supplying the tail and body of the pancreas by placing them on a stretch but it also gives immediate control of the vascular pedicle of the spleen should either vein or artery be inadvertently wounded. The tributary vessels may be divided between ligatures, either an aneurysm needle or an artery forceps being used to introduce the suture underneath the vessel. The large pancreatic artery should be secured early in the dissection. The dissection is continued until the region of the junction of the body with the head is reached. As much of the gland is removed as seems indicated by the severity of the case at hand. An assistant holds the body of the pancreas in the grasp of a rubber covered right angle forceps, just tightly enough to control bleeding. The pancreas may then be divided with a V type incision and the stump closed with either an interrupted mattress suture or running lock stitch, giving satisfactory hemostasis. A rubber tissue drain is introduced to the bed of the resected portion and the gastrocolic omentum is closed loosely about the drain. After operation the blood sugar should be maintained at normal levels by the administration of carbohydrates.

Surgical Aspects of Bleeding Gastric Ulcer—Westermann states that of the cases of gastroduodenal ulcer seen at the hospital during the past ten years about 12 per cent have been complicated by hemorrhage. In 75 per cent of these cases the hemorrhage has been massive and recurrent. In every case transfusion has been given at least once, and frequently more often, either during the course of a medical regimen or as a preoperative or postoperative measure. These records show that transfusion has been completely ineffectual as a means of stopping hemorrhage. The advisability of operation during the hemorrhage is debatable. However, hemorrhage of such proportions elsewhere in the body is always treated as a surgical emergency. Patients operated on under these circumstances have survived. One immediate death occurred in a case complicated by carcinoma of the pancreas. In each instance in which the operation performed was of the indirect type the hemorrhage continued. Westermann is of the opinion that immediate surgery of the direct type is justifiable in a large percentage of these cases and will prove permanently successful. The presence of the lesion can be determined only by careful inspection at operation with the duodenum open. Preoperative and postoperative transfusions are an absolute requirement of this procedure. Ten patients in this series died in the hospital from continued hemorrhage while receiving most rigid medical treatment and, in many instances, daily transfusions. The source of massive hemorrhage that complicates gastroduodenal ulcer is from the posterior surface of the duodenum in a large majority of cases. The blood supply of this area makes gross hemorrhage possible without deep penetration of the wall. Exploration of the open duodenum is necessary to determine this source in all cases except those in which there are large penetrating ulcers of the crater type. Preoperative diagnosis is usually definite in these cases, but diagnosis of the posterior surface ulcer is extremely difficult and cannot be accurate.

Diathermy for Carcinoma of Bladder—Counseller and Braasch point out that the use of diathermy in the surgical management of carcinoma of the bladder is gradually being extended, for it has brought within the field of successful treatment cases in which the condition formerly would have been regarded as inoperable or the growth as nonresectable. Seventeen patients whose condition was considered inoperable were treated extensively with diathermy alone, and fifteen of the seventeen lived more than five years. The two others have recently died from unrelated conditions. Tumors of the bladder that are comparatively small and are of a malignancy graded 1 or 2 are usually controlled by transurethral electrocoagulation. Some of the early circumscribed lesions that are graded 3 or 4 and that can be seen easily and give no clinical

evidence of infiltration may be treated similarly. The more extensive, highly malignant lesions and the widespread lesions with low degrees of malignancy are attacked preferably by the suprapubic route. Whenever the lesion can be completely removed surgically by either segmental resection or excision this is the operation of choice. For the inoperable lesions of both high and low grades, confined to the base, electrocoagulation is used. The small number of recurrences and the lack of deformity and infection of the bladder would recommend this method of treatment. In some instances these procedures may be combined with the application of radon seeds or of needles containing radium. The advantages of diathermy as a transvesical procedure for inoperable or nonresectable lesions of both high and low grades have not been sufficiently recognized.

The Arsenic Problem.—Reuter cites a probable case of arsenical dermatitis caused by wearing a black woolen suit. Arsenic was found in the urine and hair of the patient and in the suit. Recovery occurred when the patient discontinued wearing the suit and when local treatment of the skin was instituted. The presence of arsenic in excretions is discussed. There are no definite criteria by which to identify arsenic as a cause of disease in a given case. At present the diagnosis in obscure cases of arsenical poisoning rests on presumptive evidence. A general rule regarding the behavior of arsenic within the body is of little value, because in many persons the biochemical reactions are exceptional. Patients who suffer from symptoms of arsenic poisoning are exceptions in that they manifest a hypersensitivity to arsenic. Legally, it is difficult to state whether or not arsenical poisoning has been the cause of death, even though the amounts of arsenic found in the tissues and excretions are the same or less than those cited as normal values. The use of arsenic as a contaminating factor in foods or drugs should not be permitted, since no limit of tolerance for arsenic can be established for all persons.

Treatment of Acne and Furunculosis.—Goodman studied the effect of intravenous and local injection of physiologic solution of sodium chloride for the relief of pustular acne and furunculosis, treating several hundred patients. The pustular elements have always receded under this type of treatment. The large pus pockets of the condition sometimes called cystic acne have cleared and remained clear. Furuncles likewise are amenable to this form of therapy. It seems to make no difference whether the furuncle is in the frank pustular phase or in the stage before ripening. The first injection was 100 cc, which was increased by 50 cc until a maximum of 250 cc. was reached. A few patients were given 300 cc. There were no ill effects. The injections were carried out by the gravity method. If the patient had only one or two pus pockets the solution was injected locally directly into the mass of pus. Injections were made around the inflammatory base as well. The amount varied with the quantity that could be injected. If there was an aperture in the pustule the solution acted as a means of irrigation. Recently Bloom reported excellent results in the treatment of certain skin conditions including acne from the use of calcium chloride intravenously. Patients with pustular acne were relieved of the pus pimples when

given intravenous injections of physiologic solution for such unrelated conditions as vascular diseases of the lower extremities. The relation of a high sugar content to a low salt content may be found to be constant for infections. Persons with frank diabetes are prone to have pustular infections of the skin. Intravenous injections of physiologic solution of sodium chloride may be indicated in such cases.

Glomal Tumor.—Raisman and Mayer add three cases of glomal tumor to the twenty-six cases previously reported. This benign tumor develops from a structure normally present in the skin and known as the glomus. It is probably identical with the "painful subcutaneous nodule" reported by Wood in 1812, referred to by others. The authors collected thirty-three instances of "probable but unproved cases of glomal tumor." The glomal tumor is small, usually not more than half an inch (1.27 cm.) in diameter, of slow growth and long duration. It may be situated in any part of the body, but the favorite site is beneath the nail. There it gives rise to pain of varying intensity and radiation. In the severe cases the pain is agonizing almost paroxysmal, and radiates upward to the shoulder, even to the heart. When the tumor is not subungual, the pain is usually much less severe. Changes of temperature, particularly cold, increase the severity of the pain. Invariably the tumor is sensitive to pressure. In some cases it is associated with neurologic or vascular changes, such as hyperesthesia and increase in the temperature of the skin. In two cases there was slight atrophy of the entire arm. Examination reveals a pea-sized tender tumor, which when subungual, has almost always a peculiar bluish tinge showing through the translucent nail. A roentgenogram may show a minute crater-like depression of the dorsal cortex of the terminal phalanx. The only effective treatment is excision by knife or by endothermy. If the tumor is subungual, exposure is secured by removal of a portion of the nail, which in many cases regenerates normally. The tumor may be encapsulated as in the majority of cases, or diffuse as in one of the present cases. No metastases or recurrences after excision have been reported. Invariably pain has disappeared after removal of the tumor. Glomal tumor is easily differentiated from most of the cutaneous neoplasms. Only the unusual single small neuroma, superficially located and the subungual melanoblastoma may cause difficulty. This extremely malignant tumor at one phase of its development is characterized by a bluish black spot beneath the nail which might be mistaken for a glomus. Operation and microscopic section will at once make the differential diagnosis possible.

Vaso-Orchidostomy with Interposed Spermatocoele—Wilhelm has devised a procedure for vaso-orchidostomy that entails the creation of an artificial spermatocoele, which he believes will increase the percentage of success of operations to reestablish the seminiferous channels and more nearly reproduces the normal anatomic conditions. The entire spermatogenic tissue should be used. The testicle should not be damaged. The site of the anastomosis should be completely epithelial, so that a minimum of scar is formed. A funnel-shaped sac lined with epithelium, analogous to a spermatocoele, should be established to unite the larger cut open surface of the tubules of the epididymis or of the rete to the smaller divided end of the vas deferens. Following experiments on animals, the operation for the reestablishment of the seminiferous channels was carried out in two stages. The first stage consisted of permanent vasostomy. After complete healing had taken place, the second stage, vasosac orchidostomy, was performed.

Gangrene of Buttock and Perineum Due to Endamoeba Histolytica—The Melneys discuss a case of gangrene of the buttocks, perineum and scrotum from the clinical, bacteriologic and pathologic standpoints, and reach the conclusion that it was due primarily to the lytic action of *Endamoeba histolytica*. This case has been studied carefully with anaerobic bacteriologic technic, thus ruling out the presence of the micro-aerophilic nonhemolytic streptococcus, which is the essential organism in the progressive postoperative synergistic gangrene with which this disease might be confused. The patient made a rapid recovery following the complete excision of the lesion, the administration of a course of chiniofon and emetine hydrochloride, the local application of zinc peroxide and the application of skin grafts. In this case there was relatively little gangrene of the skin and the line of demarcation was relatively smooth and sharply outlined, the margin of skin outside the gangrene was not raised, there was no red zone and the wound was not extremely tender. The margin of the skin elsewhere was extensively undermined and the granulating base of the ulcer was rough and shaggy with necrotic tissue adherent to it. Although the clinical appearance of the lesion was quite different from that seen in cases of postoperative synergistic gangrene, other cases of amebic ulceration of the skin may not be so distinctive in their clinical appearance. In some cases of bacterial gangrene, amebas may be present as contaminating organisms without taking part in the gangrenous process. In other cases both factors may operate and change the characteristic clinical picture accordingly. The bacteriologic study confirmed this differentiation, for in the synergistic type of gangrene the essential organism, a micro aerophilic nonhemolytic streptococcus, may always be found in pure culture of material from the area just outside the margin of the gangrene and is associated with *Staphylococcus aureus* in the gangrene. The nonhemolytic streptococcus was cultivated only from material in the zone outside the gangrene. The amebas were found in the advanced zone of infection, while the bacteria were in the rear.

Effect on Blood Chemistry of Continuous Suction with Nasal Catheter—Northrop studied the effect of continuous drainage of the stomach and duodenum through a nasal catheter in twenty-five patients, twenty-four of whom were operated on. Continuous suction applied through a nasal catheter causes a drop in the blood chlorides, an elevation of the carbon dioxide-combining power toward or into alkalosis, an elevation of the hemoglobin content of the blood and an increase in the red blood cell count. The marked changes in the chlorides, hemoglobin and red cell content of the blood and the changed carbon dioxide-combining power accompanying continuous lavage of the upper intestinal tract produce few, if any, untoward symptoms. Of the various methods of administering para-oral fluids, continuous venoclysis appears to be most effective in controlling the changes in the blood incident to continuous duodenal suction. Administration of the aspirated intestinal contents in the form of retention enemas does not cause rectal irritation and deserves further study as a means of combating postoperative dehydration and the loss in chlorides and the alkalosis incident to obstruction of the intestine and continuous lavage of the stomach. The use of a properly functioning nasal catheter

with applied suction is an efficient way of controlling postoperative nausea, vomiting and distention and should be used prophylactically in cases in which this triad is anticipated. A case of obstruction of the intestine with recovery under duodenal suction is reported.

Treatment of Menorrhagia and Metrorrhagia by Anterior Pituitary-like Hormone—Henderson treated thirty-nine cases of menorrhagia and metrorrhagia, presumably due to endocrine unbalance, with the anterior pituitary-like gonadotropic hormone from the urine of pregnancy, thirty-one patients were relieved of the menorrhagia and twenty-five had a complete return to normal menstruation. Of eight patients who failed to respond to treatment, four were proved to have local pelvic lesions sufficient to cause the complaint. Successful results from this form of therapy can be obtained only in the absence of pathologic lesions of the genital tract. Moderate diffuse enlargement of the uterus is frequently encountered in functional bleeding and is not a contraindication to hormone therapy. Harmful effects from the administration of anterior pituitary-like hormone are considered unlikely and are outweighed by the excellent therapeutic results. Improvement in the patient's general sense of well being after treatment is noted, and frequent relief of dizziness, when associated with menorrhagia, is observed. More exacting methods of diagnosis of pituitary and ovarian dysfunction are necessary before the full value of anterior pituitary-like hormone therapy will be realized.

Fractures in Distal Third of Femur—Fractures of the distal third of the femur, under which category Anderson classifies the intercondylar and supracondylar forms, no longer prove

difficult to manage when one is employing a method of fracture treatment the chief principles of which are (1) a new and simple means of overcoming the deformity caused by the gastrocnemius and allied muscles and (2) the utilization of the well leg for countertraction. A working analysis of this mode of reducing supracondylar fractures includes correcting the posterior displacement of the distal fragment by wire or pin transfixion, which also acts as a traction agent, incorporating this transfixion in a plaster-of-paris cast to prevent recurrence of posterior deformity and to supply a means of immobilizing the fracture, and using an original splint, whereby only the well leg is required for countertraction. The author's technic differs in many respects from the prevailing manner of treating these fractures. Traction is not applied with the knee joint in flexion, as it is not necessary here to relax the gastrocnemius on the contrary, by immediate anterior replacement and fixation of the distal third the lower extremity is held with the knee in full extension, thereby eliminating delay in completing reduction. Under the current mode these fractures call for the maximum of after-care, while this incorporated pin method requires minimal attention. For this type of fracture it is obligatory to do more than to correct the shortening and to overcome the lateral displacement, it is necessary to overcome the posterior displacement of the distal fragment, besides correcting the plantar contraction of the foot. The steps of the procedure and the after-care are outlined.

Carcinoma Engrafted on Actinomycosis—Ruby believes that carcinoma of the cheek, mouth and jaw is usually engrafted on a previous irritant condition. Syphilis is usually present, but its etiologic importance is not fully understood. Tobacco was used in just about the percentage of cases of cancer of the mouth as in all men regardless of a malignant condition. Roentgen treatment to be successful must be massive—that is, a single lethal dose seems to be best in a case in which the involvement also includes an irritant like the actinomycosis. The efficiency of radical surgery is doubtful to add to the patient's comfort, even though it might somewhat prolong his life. A case is reported in which all the predisposing causes

were present, but it was only after an attack of actinomycosis that the malignant condition was manifested. Leukoplakia was present, but so were the characteristic sulphur granules and the ray fungus. Also, as typical sinuses appeared below the mandible, the watery yellowish discharge contained the granules in amazing numbers. When after eight or nine months the case was reviewed, the actinomycosis had disappeared but the leukoplakia and the carcinoma were still present.

Use of Sodium Formaldehyde Sulphoxylate in Acute Mercury Poisoning—Rosenthal outlines the use of formaldehyde sulphoxylate in acute mercury poisoning on a basis of its pharmacologic behavior. In its toxic action mercury produces cellular damage which, once sustained, will not be greatly benefited by this therapy. If sufficiently large doses of sulphoxylate are given by mouth it will pass throughout the alimentary canal and reduce any mercuric chloride to mercurous compounds, which are relatively harmless in the digestive tract. The oral administration of the antidote as early as possible is therefore of the greatest value because of the action on mercury and because of the local protection afforded the alimentary canal. Following intravenous injections of the drug, the blood serum will promptly reduce mercuric chloride to brownish black mercurous compounds. Intravenous therapy will prevent renal injury from mercuric chloride given subcutaneously. It will antagonize intravenous injections of mercuric chloride if injected before the mercury, treatment subsequent to intravenous injections of mercury is much less effective because of the promptness with which cellular injury is produced by this method of intoxication. The purpose of intravenous therapy is to protect the kidneys from any mercury in the tissues or alimentary tract.

that is not promptly reached by the oral therapy. It is on this basis that the administration of sulphoxylate has been arranged so that effective amounts will be present in the body for from ten to twelve hours. No toxic effects from the treatment have been encountered in fifty human cases. A limitation of the dose and time of administration of the second injection of sulphoxylate has been suggested, however, in order to lessen such possibilities. The technic suggested for treatment of mercuric chloride poisoning in adults is: 1 Gastric lavage is done with a 5 per cent solution of sulphoxylate, about 200 cc being left in the stomach. 2 Immediately following this, 10 Gm of the drug is dissolved in from 100 to 200 cc. of distilled water, to be slowly injected intravenously, from twenty to thirty minutes being permitted for the injection. 3 In severe cases the intravenous injection is repeated from four to six hours following the completion of the first injection, from 5 to 10 Gm being injected. 4 If colitis develops later, high colonic irrigations with a 1, 1,000 solution of sulphoxylate is indicated.

Phrenic Exeresis in Conjunction with Pneumothorax Therapy—Pollock and Forsee believe that hemidiaphragmatic paralysis is of value as a supplement to artificial pneumothorax therapy when additional pulmonary compression and relaxation are required for cavity obliteration because of pleuropulmonary adhesions. Artificial pneumothorax complicated by acute pleuritis with or without serous effusion frequently ends in obliterative pneumothorax. Untimely obliteration of the pneumothorax space with pulmonary reexpansion will end in disease progression, and some procedure of compression therapy should be substituted for the pneumothorax lost through obliteration. The authors advocate that the next procedure instituted should be diaphragmatic paralysis. After successful pneumothorax, diaphragmatic paralysis is indicated as a pre-expansion procedure. The elevation of the diaphragm decreases the size of the hemithorax and thus reduces the degree of pulmonary reexpansion required, prevents mediastinal retraction and causes a permanent continuation of some compression and relaxation. There is also the safety factor of decreased pulmonary function. Hemidiaphragmatic paralysis aids in compression and relaxation when pneumothorax is of an unsatisfactory character because of pleural symphysis over the involved lobe or lobes. This procedure may prevent recourse to radical surgical collapse. Hemidiaphragmatic paralysis is indicated when artificial pneumothorax, after a sufficient period, fails to obliterate midlung cavities, though no offending pleural adhesions are evident by roentgen examination. Diaphragmatic paralysis is of value when factors are present that tend to make artificial pneumothorax unsatisfactory and when though the pneumothorax therapy has been successful, reexpansion of the compressed lung is contemplated. When factors are present that interfere with compression and relaxation of the treated lung, diaphragmatic paralysis has proved of value. If it is of value under unfavorable conditions, its value increases when favorable factors exist, and, since it is of value as a preexpansion procedure, the authors see no reason why practically all cases of artificial pneumothorax should not be supplemented by diaphragmatic paralysis.

Abnormal Bleeding in Women After the Age of Fifty—Pemberton and Lockwood investigated a consecutive series of 596 patients treated at the Free Hospital for Women with abnormal uterine bleeding as one of their complaints, 293 of whom were found to have benign lesions at the first operation. They conclude that, when the clinical evidence points toward the presence of carcinoma of the endometrium, a hysterectomy should be performed in spite of negative results by curettage, particularly when the patient is a nullipara who has passed the menopause. The treatment of elderly patients with uterine bleeding of any type is not complete without biopsy or thorough examination of the cervix to rule out carcinoma, even though there may be an obvious lesion elsewhere in the genital tract. About 50 per cent of women who report abnormal bleeding after the age of 50 will prove to have cancer as a cause. Some authorities have advocated doing a complete hysterectomy without curettage in any patient who bleeds after the menopause, on the ground that she almost certainly has cancer of the endometrium. In the present study there were twenty seven patients with polyps who would have been operated on unnecessarily if an intra-uterine examination had not been done.

Arthritis and Tonsillar Infection—To learn more about the association between tonsillar infection and joint disorders, Nissen studied nearly 500 arthritic patients. Even without recognized association between infections of the upper part of the respiratory tract and joint infection, such association may be present. Proof of this depends on intensive study of the individual to determine three factors: 1 Recognition of obvious and concealed chronic infection in the nasopharyngeal tissue. The two most common are unmistakable, the acutely infected tonsil and the red hypertrophied chronic tonsil. The third is possibly of greater importance and is often missed unless the patient is seen frequently, and the appearance, subsidence and reappearance of signs of infected lymphoid tissue are noted. On examination of this type of throat a purplish red discoloration is seen on the anterior tonsillar pillar, along the edges of the soft palate and at times in the uvula. These local changes are

constant to a certain degree (the dusky discoloration being present at all times) but show varying reactions to exogenous and endogenous infection. During such reactions the tonsillar poles become prominent and more inflamed, but this is noted only if the upper part of the tonsil is exposed. The duration of the reaction is short if the excitor is endogenous, long if of exogenous origin. 2 Recognition of joint and other systemic infection. This depends on thorough physical, laboratory and roentgen examinations. 3 Determination of association between local and joint and systemic infection by extensive and prolonged study of each individual patient.

Prevention of Intranasally Inoculated Poliomyelitis of Monkeys—Armstrong and Harrison observed that the instillation of 4 per cent sodium aluminum sulphate into the nostrils of monkeys resulted in the survival of seventeen of a group of twenty three animals, while only three of a group of nineteen nonprepared controls survived similar intranasal inoculation with poliomyelitis virus. Poliomyelitis tended to develop later and to run a slower course in the alum prepared group than in the nonprepared controls. The protective action of the alum solution is believed to be due to an alteration that decreases the permeability of the mucous membrane of the nose rather than to an antiseptic action.

Use of Below Freezing Temperatures for Maintenance of Meningococcus Cultures—Pabst preserved ten chosen strains of meningococci in neutral glycerin at -15°C for two years with no apparent change in viability, morphology or serologic or biochemical characteristics. Two hundred and twenty-three strains have been stored at this temperature on dextrose agar slants, both with and without glycerin, with no appreciable loss of viability in the eight months during which they have been under observation.

Hyperparathyroidism—The diagnosis of hyperparathyroidism Lahey and Haggart state, depends primarily on (1) an analysis of the chemical observations and (2) a survey of the roentgenograms of the bones of the skeleton and also of the kidneys. With the diagnosis of hyperparathyroidism estab-

lished, the parathyroid adenoma should be found and removed. Failure to find parathyroid adenomas in many cases will be due to failure to realize the frequent atypical location of the parathyroids and failure to investigate the possible atypical locations for a possible parathyroid adenoma. With the prethyroid muscles severed, the middle thyroid veins are ligated between clamps so that the lateral vascular attachments of the thyroid to the internal jugular vein are severed. The outer border of the thyroid is then grasped with forceps and rotated inward. The internal jugular vein and common carotid artery are completely separated from the back of the thyroid and the inferior thyroid artery completely demonstrated as a trunk where it passes behind the common carotid artery. The back of the gland is inspected, and if a tumor cannot be seen the gland is palpated for such a tumor within the gland. An adenoma of a parathyroid usually converts that structure into a globular mass and changes its color to a pale white rather than the brownish color characterizing the typical normal parathyroid. Should no parathyroid adenoma be demonstrable on this exposure, the inferior thyroid artery must be completely dissected up to its entrance into the thyroid gland. The recurrent laryngeal nerve must be found and dissected up to its passage behind or in front of the inferior thyroid artery. If still no parathyroid adenoma is found, one must expose the groove between the trachea and the esophagus in the region of the inferior thyroid artery. If still the adenoma is undemonstrated, the superior thyroid artery should be ligated and the upper pole of the thyroid turned downward, so that the region where it rests against the thyroid cartilage may be inspected. At this point caution must be exercised, as the recurrent laryngeal nerve enters the larynx here, at the point where the lowest fibers of the inferior construction are inserted into the horn of the thyroid cartilage. If the tumor is still not found, the thyroid should be palpated through and through between the thumb and the forefinger and any discrete globular nodule within the gland exposed by an incision into the gland removed and submitted to the pathologist for immediate frozen section report. If failure to demonstrate the parathyroid tumor persists the search is continued in the bundles of the superior thyroid vessels, out along the main trunk of the inferior thyroid artery, behind the esophagus and along the inner aspect of the upper pole. The isthmus is palpated against the trachea. If a pyramidal lobe is present it is exposed and palpated throughout its extent. If the evidence of the existence of hyperthyroidism is certain and still no parathyroid tumor has been found, and if digital palpation of the superior mediastinum demonstrates no palpable parathyroid tumor, the manubrium of the sternum may be removed to facilitate a visual search for a mediastinal parathyroid adenoma. Should exposure of all these regions fail to demonstrate an adenoma of a parathyroid, it then becomes justifiable to remove and submit a normal appearing parathyroid to the pathologist for decision as to the possible presence of hyperplasia of the parathyroids.

Electrosurgical Aseptic Intestinal Anastomosis—Wadhams and Carabba do not agree with Ward that the electrocoagulation procedure for intestinal anastomosis cannot be relied on for the stomach with its redundant mucosa. The failure is one of lack of properly performing the electrosurgical technic, especially as to the depth and strength of the current and the degree of coagulation. In the authors' experience the technic of Briggs and Whitaker, calling for only one row of sutures, is adequate. In retrospect there are only extremely rare instances in which immediate anastomoses are necessary. In cases in which immediate intestinal drainage is necessary, temporary ileostomy, colostomy or appendicostomy may be performed. In cases of intestinal resection, the anastomosis can be performed below the lumen of the resected intestine and the lumen allowed to drain externally while the anastomosis forms and begins to function. The authors have not had a case of secondary hemorrhage in fifteen consecutive operations by their method, which they describe. All the animals were carefully watched after operation and at necropsy for this complication. They believe that the possible applications of the technic to the human being are: 1 Gastro-enterostomy—by electrocoagulation when such a procedure is necessary in repairing a per-

forated duodenal ulcer complicated by stricture 2 Lateral anastomosis after resection of segments of the intestine secondary to partial gangrene of a portion of the intestine, as in strangulated Richter's hernia, gangrene due to bands, or femoral hernia The two open ends of the loop are left externally for drainage until the obstruction is relieved. The fistula can be then allowed to close spontaneously or repaired secondarily This procedure can be applied in performing an enterocolostomy 3 Ileosigmoidostomy as a preliminary procedure to resection of the cecum and ileosigmoidostomy of choice with a temporary colostomy or appendicostomy 4 Completion of the Mikulicz operation in the first stage of the operation, with elimination of the secondary clamping 5 Cholecystogastrostomy or enterostomy 6 Anastomosis of the ureters to the large intestine. 7 Without obstruction, primary resection of the large intestine with side-to-side anastomosis, instead of the Mikulicz operation. The authors performed fifteen consecutive and diversified anastomoses on the dog and one on man successfully by the electrocoagulation technic without mortality, leakage, infection or hemorrhage.

Operation for Tuberculous Empyema—Cloesser's desire to obviate a drainage tube led to an operation that has proved of use in a number of secondarily infected tuberculous empyemas. It has been used in a few obstinately toxic tuberculous empyemas in which no pus forming organisms could be found. The operation causes the underlying lung to expand, it is therefore not applicable to empyemas in which the lung is so badly affected that expansion to any degree seems inadvisable. The question of applicability must be decided by clinical pulmonary symptoms and especially by roentgenograms taken prior to the appearance of the complicating empyema. Under local anesthesia a U-shaped flap of skin and subcutis is outlined about half way between the posterior axillary line and the line of the inferior scapular angle. The flap has a base about 2 inches wide, which lies about one rib higher than the bottom of the empyema cavity, so that the rising diaphragm may not stop drainage, it is about $2\frac{1}{4}$ inches long, the length of two ribs and their intercostal spaces, long enough to reach into the pleural cavity without the least tension. The rib underlying the top of the flap is resected, the amount resected equaling the width of the flap. If the flap is too narrow and the resection too scant, drainage will be insufficient. The rib should be stripped with a cautery instead of a raspatory and the bared intercostal nerve injected with 1 cc. of absolute alcohol. The tip of this flap is turned into the chest and tacked to the pleura with one or two chromic catgut stitches, the edges of the defect in the skin are approximated with a few stitches of silk-worm. This thoracotomy needs no tube for the skin flap which lies against the soft parts of the chest keeps the wound open. It remains open until the lung reaches the chest wall, after which it spontaneously and automatically closes. It has a valve action, each cough or rise in intrapulmonary air pressure expels a little air from the thorax and causes a gradually increasing negative pressure in the empyema cavity. It is more difficult for air to enter through this valvelike wound than to escape from it. Dressings should be left in place as long as possible—for many days.

Peripheral Nerve Block in Obliterative Vascular Disease—Smithwick and White point out that peripheral nerve block is an effective method of controlling rest pain in patients with advanced obliterative vascular disease. Besides controlling pain, the circulation to the part may be increased because the anesthetic area is also deprived of its vasoconstrictor nerves. Local infection in open lesions is more easily controlled because frequent antiseptic dressings can be done painlessly. The general condition of the patient improves with the relief of pain, and other conservative measures become more effective. The operation requires careful technic and asepsis and should be done in multiple stages. The nerves may be either injected with alcohol or crushed. The latter method is more simple and equally effective, although the nerves regenerate more rapidly. The authors believe that this procedure has more than halved the number of necessary major amputations and more than doubled the number of successful minor amputations. It also has increased the number of cases in which no amputa-

tion is necessary. They emphasize the striking reduction in bilateral major amputations in their forty five cases. The results are better in the patients with thrombo-angitis obliterans than in the arteriosclerotic group. Patients with pulsation of the popliteal vessels do better than those in whom the vessel is obliterated at this level. Amputation of uninvolved toes is an effective prophylactic procedure in selected cases. If the vasomotor index is high, lumbar ganglionectomy should be done after the peripheral nerves have regenerated in certain cases. Unless hopeless gangrene or infection sufficient to endanger the life of the patient is present, this operation should be tried before a major amputation is resorted to. It is not indicated in the early treatment of obliterative vascular disease but should be used in advanced stages after other conservative methods have proved inadequate.

Leiomyoma of Gastro-Intestinal Tract.—Jones presents two cases of leiomyoma of the gastro-intestinal tract observed during the last two years. He states that gastro-intestinal leiomyomas may be intraluminary or extraluminary, depending chiefly on the layer of muscle from which they are derived. For example, a tumor arising from the muscularis mucosa would more than likely be intraluminary and pedunculated, whereas one springing from the external layer would develop between the layers of the mesentery or, if opposite the mesenteric attachment, would by stretching the peritoneum become subserous. Many leiomyomas of the gastro-intestinal tract remain dormant and never produce symptoms worthy of note. On the other hand, they are capable of a wide variety of complications, depending on the location and size of the growth as well as the degree of malignancy. Submucous growths, for instance, are particularly prone to ulceration and hemorrhage. Such tumors may be the cause of gastro-intestinal bleeding of obscure origin. Ulceration may result in perforation and peritonitis. In the stomach, a submucous pedunculated growth may produce an intermittent pyloric obstruction, and in the small and large intestine it is not uncommonly the cause of intussusception. Subserous growths are rarely pedunculated, and Wolfer states that they may vary in size from that of a cherry to that of a mass filling the entire abdomen. Adhesions often develop, as the result of which the tumor may become fixed to the viscera or to the abdominal wall, thereby increasing the possibility of intestinal obstruction. In the case of the small intestine, angulation may be produced by the weight of the tumor, even in the absence of adhesions. When the growth is of the mixed type and encroaches on the mucosa, ulceration and hemorrhage may result, as it does in the intraluminary type. Leiomyoma should be considered in any case presenting vague abdominal symptoms, when a history of intermittent attacks of intestinal obstruction is obtained or when the case is complicated by gastro-intestinal hemorrhage of obscure origin. More often than not the tumor is not palpable, in which case the roentgenogram is of great value in the diagnosis. The treatment is surgical, the technical procedure depending on the immediate complications to be dealt with, the location of the growth, whether or not it is malignant, and in benign cases the risk of the operation versus the risk of carrying the tumor.

Fractional Gastric Analysis in Diseases of the Skin.—Brown and his associates performed gastric analyses in 150 cases of rosacea, and compared the results with those of a previous investigation of fifty cases. For comparison, gastric analyses have been performed also in 166 cases of dermatoses other than rosacea. The percentage of cases showing achlorhydria and extreme hypochlorhydria is lower in the rosacea group, viz., 28 per cent, as compared with 35 per cent in other dermatoses. Symptoms of gastric disturbance were present in 61 per cent of a group of seventy-five patients with rosacea. The severity of the symptoms varied considerably in degree. In some they were negligible and in others they amounted to actual pain. The most common complaint was a sensation of fullness after food, with flushing of the face. The degree of flushing also varied greatly. A much more extensive study of the gastric analysis has led to the conclusion that marked subacidity is not a feature peculiar to rosacea as was originally thought. A degree of subacidity seems to be a feature of chronic dermatoses in general. The observations do not detract from the well established fact that strict dietetic treatment in combination with large doses of dilute hydrochloric acid brings about marked improvement in rosacea. A subacidity is frequent in rosacea and in other chronic dermatoses. It frequently follows the infectious fevers. In pernicious anemia and subacute combined sclerosis, achlorhydria is the rule. It is a feature also of the type of anemia described variously as microcytic, nonmegalocytic or simple achlorhydric anemia, and of the condition known as gastrogenic diarrhea and of certain glossitic and ulcerative disorders of the mouth. According to Ryle, the gastric habitus of the individual is closely related to the physiologic habitus. The one possible explanation of the subacidity found in chronic dermatoses is that the pain, discomfort or itching of a chronic dermatosis in time would tend to produce a depressed, debilitated, hypotonic individual. In the allergic complaints of the authors' series (Besnier's prurigo), in which one would expect the hypotonicity and the hypoadrenalism to be most marked owing to the long duration and distressing nature of the complaint, the subacidity was least marked of all the dermatoses. The rosacea patient, according to Rulison, is typically a person with poor muscle tone and a low blood pressure. It is likely that some degree of gastritis is always present in view of the dietary indiscretions indulged in by the patient. Although the duration and the severity of the disease in rosacea appear to bear but little relation to the gastric hydrochloric acid content, this may be explained by the constitutional factor. In a hyperthemic individual with hyperchlorhydria the presence of chronic gastritis may lead to reduction of the gastric acidity without bringing it below the level of hyperchlorhydria.

Tonsillitis and Albuminuria.—In 354 cases of tonsillitis de Wesselow and his associates found 14.4 per cent that showed definite early albuminuria and 6.2 per cent late albuminuria.

From the urinary and clinical observations it would seem probable that focal nephritis occurred in thirty-five (10 per cent) and diffuse glomerulonephritis in at least three (0.8 per cent). No correlation was found between the predominance of hemolytic streptococci in the throat at the time of the acute infection and the incidence of focal nephritis. Seasonal variations of external temperature did not appreciably affect the incidence of early or late albuminuria. The incidence of predominant hemolytic streptococcus infection in the throat was not greater in those patients who afterward complained of rheumatic pains than in the general series.

Tuberculous Meningitis in Children.—Blacklock and Griffin say that tuberculous meningitis is the most frequent form of meningitis in childhood. The primary site of infection in a series of 241 cases of tuberculous meningitis under 13 years was most frequently thoracic (73.9 per cent), then abdominal (22.8 per cent), of the cervical glands (2.1 per cent) and unknown (1.2 per cent). There was little difference in the sex distribution. Of the patients, 85.5 per cent were less than 6 years of age. The seasonal incidence was highest in the late spring and early summer months. The frequent association of tuberculous meningitis and generalized miliary tuberculosis is discussed, either lesion alone is uncommon. Human strains were easier to isolate directly by culture than bovine. In one case, in which infection with a human strain had occurred, the inoculated guinea-pig gave a negative result whereas the cultures were positive. From a clinical series of cases of cerebral tuberculosis seventy-two strains were isolated, of which 18.1 per cent were bovine, and from the primary lesions in a necropsy series 11.4 strains were obtained, of which 24.6 per cent were bovine. The highest percentage of bovine strains occurred in the third year of life in both series. The total bovine percentage obtained for meningitis from both series was 22.5 per cent and for all forms of cerebral tuberculosis 22 per cent. A higher percentage of bovine infections was noted in

country than in city children. Meningitis following primary thoracic lesions was nearly always due to the human type of bacillus, and that following primary abdominal lesions was usually due to the bovine type. Bovine strains were isolated in three cases of meningitis in which primary lung lesions were verified at necropsy. A case is described in which tubercle bacilli were isolated during life from the cerebrospinal fluid and in which tuberculomas were found at necropsy, but no meningitis.

Effect of Heat on Reactivity of Serum in Wassermann Reaction—Irregular results appear not infrequently in the Wassermann reaction when a 1:2 dilution of serum is employed. Fairbrother and Peeney suggest the correction of the defect by inactivation at 58°C. An explanation of this phenomenon does not readily present itself. There appears to be no doubt that with the serum dilution of 1:2 complement is not completely fixed by the combination of the antigen and the reacting substance in the serum. It has been suggested that the natural antishrimp hemolysin is the main responsible factor. If this were so it would indicate fixation of the complement during the initial incubation by the hemolysin alone rather than by the antigen serum combination. The results show in an unequivocal manner that, when a satisfactory antigen is employed, any part played by the natural hemolysin is relatively insignificant. Correction of the irregularity was frequently obtained, irrespective of the presence of natural hemolysin, by means of further inactivation of the serum at 58°C. A second heating at 56°C did not have this effect, therefore some important change had resulted from inactivation at the higher temperature. A further demonstration of this change was that the serums alone usually absorbed less complement. These results suggest that by inactivation at 58°C some alteration, probably of a physico-chemical nature occurs in the serum and that the subsequent fixation of complement by the antigen serum combination becomes greatly facilitated. In the routine test owing to some peculiarity of individual serums, complete fixation of complement by the greatest concentration of the serum in the presence of antigen is prevented. The actual nature of this peculiarity, however, except that it is corrected by inactivation at 58°C, is unknown.

Etiology of Acute Rheumatism—According to Signy and his co-workers, the deposits obtained by high speed centrifugation of pericardial fluid in cases of acute rheumatic pericarditis contain particles that morphologically resemble virus elementary bodies. Similar bodies have been found in the deposit obtained from one pleural exudate in association with rheumatic pneumonia. Relatively pure suspensions of these bodies in formal saline solution have been prepared. These suspensions are specifically agglutinated by the serums of patients who are suffering from, and successfully resisting an acute rheumatic infection. The serums of patients in whom the infection is quiescent fail, as a rule, to agglutinate these suspensions. Completely negative reactions were also obtained

with the serum of normal persons and of patients suffering from various nonrheumatic infections. It is believed that the bodies found in pericardial exudates represent the actual infective agent of acute rheumatism. The importance of streptococcal infection as a factor in the etiology of the disease is recognized. It is suggested that the lowered resistance produced by such infections enables the virus to enter the body or, if the virus is already lying latent in the tissues, allows it to assume active characters. The characteristic properties of the infective agent of rheumatism cannot be closely paralleled with those of any known virus. Some of its characters, however, are shared by a number of virus agents.

Relation Between Adenomas and Cancer of Intestine.

—In his follow up study of fifty operative cases of what was believed to be simple adenoma, Lockhart-Mummery observed that adenomas of the rectum or colon are not innocent growths and that they are merely a stage in the development of malignant tumors and should be so treated. At a certain age, some cells of the intestinal epithelium exhibit a tendency to undergo hyperplasia. This tendency is not confined to one cell or group of cells but appears to be fairly widespread, with the result that the removal of one adenoma does not prevent the development of others. The author believes that what happens when a tumor forms, is that a change or gene mutation occurs to start with in the nucleus of a single cell, resulting in an excessive rate of reproduction of that cell as compared with the reproduction of normal cells of the same tissue. The adenoma results from the excessive reproduction of this single cell. The tumor is composed of normal cells differing, as far as can be observed, from other cells only in the fact that its cells are reproducing themselves too fast. This tendency for a mutation or change of their character to take place is often, however, present in a number of different cells in a fairly wide area. The exciting cause of the change may be due to genetic instability or to some factor in the environment, and the fact that it has occurred in one cell does not prevent the same change from taking place later on in other cells. From a practical point of view, local removal of the tumor would appear to be sufficient if the patient is observed at intervals of every four months during the next five to ten years, so that fresh tumors can be removed at once before they have had an opportunity of becoming malignant. But, unless the patient is kept under observation in this way, the development of other tumors is very likely to occur unobserved. The frequency of such a happening appears to be about 50 per cent, and a considerable danger exists of a malignant condition supervening.

Primary Lymphogranuloma of Stomach: Report of Four New Cases. T. Thompson and L. H. Howells—p. 81.

Pituitary Basophilic Syndrome and Adrenal Corticogenital Syndrome—Lescher reports a case of carcinoma of the adrenal cortex, which shows all the cardinal and most of the occasional symptoms recently ascribed by Cushing to an adenoma of the basophil cells of the anterior lobe of the pituitary. Examination of serial sections of the pituitary gland showed some general increase in the basophil and acidophil cells, and at one point there was a small collection of the basophil cells 0.3 mm. in diameter. In view of the case reported and

others of a somewhat similar kind from the literature, the author concludes that Cushing's syndrome, complete in its entirety, may be caused by such diseases as tumors of the adrenal cortex, and so a clinical distinction cannot always be made between these two syndromes. Every case of Cushing's syndrome should be critically examined, including a roentgen examination of the abdomen for a shadow in the renal areas and for the position of the kidneys. While it is generally accepted that the anterior lobe of the pituitary elaborates one or more gonadotropic secretions, there is no reliable evidence to show that the basophil cells are responsible for this. What evidence there is is rather against this theory. From the study of the basophilic syndrome and from observations that an excess of basophilic cells occurs in such diseases as hypertension, vascular sclerosis and chronic nephritis, as well as in old age, it may be that the basophil cells are a source of some depressive inhibitory substance that can produce such conditions as a low metabolic rate, altered carbohydrate metabolism, obesity, lethargy and lack of sex functions.

Schüller-Christian Syndrome — Horsfall and Smith observed a case of the Schüller-Christian syndrome during two admissions to the hospital, and finally they performed a complete necropsy. Pathologic studies of the tissues indicate that the lesions are granulomatous in nature and contain large quantities of lipoids. Fractional chemical analyses of the lipoids in the lesions demonstrate the predominance of cholesterol. This confirms the work of other investigators. Fifty-nine other cases of Schüller-Christian syndrome have been collected from the literature. Thirty-six completely reported cases have been analyzed, and the disease is discussed on this basis. Although lipid granulomatosis, as used by Chester, is more accurate than the term xanthomatosis, it is suggested that the former could with more exactness be modified to cholesterol granulomatosis.

Secretion of Urine in Diabetic Coma — McCance and Lawrence state that diabetic coma may be accompanied or followed by a disorganization of renal function characterized by (1) an oliguria, which is not invariable and often transitory, (2) a retention of urea, creatinine (and probably uric acid), which may outlast the oliguria by some days (3) a retention of ketone bodies (if present), (4) a retention of sugar (if present above threshold limits), (5) a very acid urine (*pH* usually about 5), (6) a normal excretion of ammonia, (7) no loss of the acid base regulating mechanisms associated with salt excretion, (8) no constant anatomic lesion and (9) a tendency to recovery with absence of sequels. A similar and possibly identical syndrome has been encountered in two noncomatose diabetic patients and may be relatively common and be closely allied to the renal dysfunctions of intestinal intoxication and Addison's disease. The real cause is unknown. There is no specific treatment. If the patient lives, insulin and fluids (especially perhaps salines) will in time restore the function of the kidney.

Extension Plaster Casts. G. Ricunau — p. 861
Meaning of Allergy. M. Jaquerod — p. 862

Polycoric Hepatomegaly — In a previous article (*Presse méd.* 43 801 [May 18] 1935) Debré coined the word polycoria. It is derived from the Greek and means pathologic accumulation of reserve substances in an organ resulting in its hypertrophy. In the present article Debré and Sémelaigne discuss various aspects of polycoric hepatomegaly. The clinical onset is gradual, usually occurring in the first months of life. The first sign observed is increased volume of the abdomen due to enlargement of the liver. In the majority there is no other sign. The enlargement is considerable, the liver occupying at least a third of the abdominal cavity and pressing the intestine down and to the left. There is never a collateral circulation or signs of portal hypertension or ascites. Disorders of growth are present, but their intensity is variable. Biochemical studies show metabolic disturbances affecting the carbohydrates and fats. There is usually a hypoglycemia in the morning. After ingestion of dextrose, the increased glycemia is slight and slow and the return to normal is equally slow and follows a prolonged phase of hypoglycemia. In three of their four patients the lipemia was markedly high. The evolution of the disease is distinctly chronic and spreads over several years. It must be differentiated from the familial hepatosplenomegalies and the disorders of lipid metabolism. The pathologic anatomy is not yet completely known, but it may be stated that the characteristics are an enormous, smooth, pale liver of homogeneous appearance. The consistency and color on section are those of a liver affected with fatty degeneration. Microscopically, a massive accumulation of glycogen in the form of droplets in the cellular protoplasm is seen. The pathogenesis is uncertain, but the authors feel that the condition is a result of a neuroendocrine disorder affecting the glands which control carbohydrate metabolism, especially the system antagonistic to the pancreas-adrenals.

*Cause of Jaundice in Spirochaetosis Icterohaemorrhagica Inada (Weil's Disease). R. Kaneko — p. 531

Industrial Poisons as Cause of Neuritis — Isenschmid and Kunz report the history of a man, aged 56 whose occupation caused him to inhale trichlorethylene. He developed a severe retrobulbar neuritis with pupillary disturbances, paralysis of the hypoglossal nerve of the left side and polyneuritis of the nerves of all the extremities, with abolishment of the reflexes and reduction of the cutaneous sensitivity in the region of several peripheral nerves. The symptoms proved to be rather persistent and the vision seems to be permanently impaired. The authors call attention to the wide use of neurotoxic trichlorethylene, pointing out that it is employed as a fat solvent in industry as well as in cleaning fluids and other preparations that are marketed for home use.

Cause of Jaundice in Weil's Disease — Kaneko states that studies carried out by his students disclosed that the direct diazo reaction in the serum develops promptly in Weil's disease. This and clinical observations led him to assume that the jaundice in this disease is connected with the passage into the blood of the bile which is in the bile duct system. The author's student Oka made the diazo test on fifteen patients with Weil's disease and on infected animals. The reaction was always diphasic that is, the serum contained two types of bilirubin the functional and the congestive types. Oka was able to show that the bile is discharged as the result of cell dissociation. The bile passage that results from cell dissociation

tion shows the following aspects. Between the liver cells or the epithelia of the bile ducts there is a bile-colored mass, which exudes from the bile capillaries and from the lumens of the bile ducts, follows between the two cellular walls and is discharged into the yellowish perivascular edema. The author thinks that the bile-colored mass is bile. Oka observed that the only other condition in which this discharge of bile takes place is a jaundice that develops in dogs after poisoning with toluyene diamine. The author deduces from this that the jaundice in Weil's disease is likewise due to toxic action. He assumes that the toxin of the spirochetes first impairs and then dissolves the cellular cement substance. The result is cell dissociation and passage of the bile from the bile ducts into the lymph spaces and into the blood. Formerly the author assumed that the connection between the bile ducts and the blood was produced within the hepatic acini by the stasis of the pathologic bile in the impaired bile capillaries. However, Oka's studies disclosed that stasis is unnecessary and that the destruction of the cellular cement substance by the toxin of the spirochetes is the chief factor.

Intolerance to Insulin.—Beggi reports a case of diabetes in which the hypodermic injection of insulin (after the injections of insulin had been suspended for some time) was followed by the appearance of an urticarial reaction associated with edema of the face and neck. The intradermal reactions performed in the individual with various brands of insulin (Roche, Leo, Zanoni and Erba) all gave positive results. The reaction of insulin of the Serono brand produced the most marked positive reaction, manifested by the appearance of an area of erythema with a raised wheal at the site of the injection. The parenteral administration of deinsulinated pancreatic extracts (angioxil and astenil) did not produce any effects of intolerance in the patient. Experiments for the transfer of the patient's antibodies to rabbits gave the following results. The injection of a few drops of insulin of different brands in one of the ears of various rabbits, twenty-four hours after the injection of blood serum of the patient in the same ear, gave positive results with all brands of insulin, especially with that of the Serono brand. The injection of deinsulinated extracts in the other ear of each of the animals twenty-four hours after the injection of the blood serum of the patient in the same ear gave negative results in all cases. The intradermal injections of highly diluted insulin, but in increasing concentration, produced a temporary desensibilization in the patient, permitting him to continue his insulin treatment by the hypodermic route.

- Intestinal Parasitism in Children. J. M. Pardina—p. 1050
- *Cardiac Area in Rheumatic Fever in Children. J. C. Bertrand and J. R. Abdala—p. 1063

Enlargement of Cardiac Area in Rheumatic Fever.—Bertrand and Abdala say that the enlargement of the cardiac area, as determined by percussion, is a sign of value for the diagnosis of rheumatic fever in children, especially in cases of atypical forms of the disease in which the cardiac complications appear late in the disease or do not appear at all. The cardiac area enlarges more or less rapidly in all cases of rheumatic fever. In atypical cases the sign exists in the absence of the cardiac auscultatory symptoms and earlier than the appearance of changes in the electrocardiogram. The authors believe that the lack of tonus of the myocardium that results in the enlargement of the heart is due to the myocardial congestion and diapedesis originating from the impregnation of the myocardium by rheumatic toxins. Four atypical cases are reported. Two roentgenograms of the thorax of one of the patients, in whom murmurs did not exist, taken at a month's

interval revealed the extraordinary change in size of the heart in so short an interval, showing the rapid modifications that the cardiac area may undergo in exceptional cases without murmurs.

- Pathology of Bed Wetting. Z. von Guliksy—p. 81
- *Galactose Test in Children. B. Chomet—p. 86
- Atypical Diabetic Coma in Small Children. K. Hassmann—p. 91

Reticulocytes in Lymphatism.—Hülse observed a relative increase in monocytes and lymphocytes in twenty-nine children with lymphatism, although the total number of leukocytes was normal in some of these children. In some cases a considerable increase in the reticulocytes was noted and interpreted as a symptom of an anemia that accompanies the lymphatism. This mild anemia in children with lymphatism is characterized by a comparatively slight decrease in hemoglobin and in the erythrocytes and by manifestations of brisk regeneration. On the other hand, reticulocytosis was absent in some children with severe lymphatism. Consequently the author considers it doubtful whether an increase in the reticulocytes can be considered as a criterion of the existence of lymphatism.

Galactose Test in Children.—Chomet reports the results of galactose tests on sixty children. He observed that the galactosuria was influenced by the body weight. In fifteen children the galactose test was made with the same quantity of galactose (40 Gm.) that is used in adults. However, since the values showed differences that corresponded to the various weight groups and since, moreover, the results obtained in the children with icterus were not entirely clear, the author made the galactose test with 30 Gm. on thirty-eight children without hepatic disorders. He found that the children who weighed more than 30 Kg. eliminated less than 2 Gm. of galactose, while the children who weighed less than 30 Kg. eliminated less than 3 Gm. Consequently the author assumed for children with a weight up to 16 Kg., in whom 30 Gm. of galactose had been administered, an approximate threshold value of galactosuria of 3 Gm. In adults, 3 Gm. is taken as the maximal normal value with an intake of 40 Gm. The author tested the galactose reaction also in a number of children with icterus. Nearly all these children showed values that noticeably exceeded the normal values and thereby indicated hepatic impairment. This became especially plain when, in children with icterus, the test was repeated every week. As the icterus subsided, a steplike reduction in the galactosuria could be observed.

Articular Rheumatism and Pulmonary Disorders.—Rehberg thinks that infectious polyarthritis may be caused by tubercle bacilli as well as by numerous other pathogenic organisms. However, the incidence and the mechanism of the tuberculous origin have not been completely clarified as yet. Löwenstein's bacteriologic blood tests for the detection of tubercle bacilli have led some investigators to ascribe nearly all cases of polyarthritis to the tubercle bacillus, while others consider the tuberculous etiology of rheumatism extremely rare. The author describes several cases of pulmonary tuberculosis that concurred with polyarthritis. In one case the polyarthritis took a subacute course, the symptoms lasting about three months. The arthritic symptoms were refractory to salicylates, but they gradually disappeared following the subsidence of the glandular swellings. In another case the tuberculous articular rheumatism took a chronic course. The author calls attention to diagnostic difficulties, stressing that it is necessary to differ

entiate between caseous degenerative articular tuberculosis, tuberculous polyarthritis and ordinary infectious polyarthritis in a tuberculous organism. In discussing the factors on which the diagnosis of a tuberculous polyarthritis can be based, he expresses the opinion that the bacteriologic demonstration of tubercle bacilli in the blood (according to Löwenstein's method) is not yet suited to decide the diagnosis. The detection of tubercle bacilli in the articular punctate is of greater importance. The diagnostician must give his attention chiefly to the type of the primary tuberculous disorder and to the relation between the rheumatic symptoms and the beginning and further course of primary tuberculous disease. In the two aforementioned cases the parallelism was so noticeable that it was decisive for the diagnosis. However, when this parallelism is absent the diagnosis becomes doubtful. The author illustrates this in a case report. The absence of signs of new inflammatory or hematogenic processes made it doubtful that the articular disorder was of tuberculous origin, in spite of the fact that extensive tuberculous processes existed in the lungs. The assumption of an ordinary infectious polyarthritis was corroborated by the prompt action of salicylate. The author describes the history of a patient with bronchiectasis and with subchronic impairment of several joints in whom an acute articular rheumatism developed following an injection of histamine. He considers this articular rheumatism an allergic inflammation in an organism that had been sensitized by proteinic decomposition products developing in the bronchiectatic cavities.

Flocculation Capacity of Serum in Tuberculosis—Molnár gives a review of the tests that have been suggested for the determination of the colloid lability in tuberculosis. These tests require large quantities of blood serum and they do not give entirely reliable results. The greatest disadvantage is that they are adapted to a certain point of the protein curve, so that only a single protein fraction can be determined with them. This disadvantage was eliminated by a quantitative micro-analytic method, which was developed by Darányi in 1931. The author found this method reliable but too complicated. He developed a simpler method and used Nissl's centrifugation tubes of 7 cc. capacity, which have a narrow lower portion of 0.5 cc. capacity with scale division. For the precipitation of the globulin fractions of the serum he found aluminum sulphate, in the 0.05 per cent solution as suggested by Matéfy, most suitable. Like Matéfy, he adjusted the test in such a manner that there develops no precipitate in healthy persons, whereas large amounts of precipitate appear in patients in whom tissue decomposition takes place. The author made this test approximately 2,000 times, chiefly on the serums of tuberculous patients. The reaction showed high values in thoracic empyema and in extensive cavernous tuberculosis of the exudative type. The highest values were obtained in carcinoma and in pleural and peritoneal exudates. In a number of cases the author observed that, if the reaction continued to show high values after pneumothorax treatment, exudates often developed later, whereas no exudate developed in cases in which the reaction disclosed improvement. High values were observed also in syphilis and in some instances in which clinical observation indicated only emphysema or diffuse bronchitis. In tuberculosis of the bones, higher values were obtained than were disclosed with other colloid reactions. Contrary to expectation, the values were low in catarrhal icterus, probably as the result of the presence of salts of the bile acids. If care is taken that centrifugation is continued for exactly two minutes at 1,500 revolutions, the reaction is well suited for comparative tests.

- Extensive Deposits of Lipoid Protein Crystals in Interstitial Substance of Kidney in Nephrosis with General Amyloidosis. E. Randerath—p. 911

Allergens in Rheumatism and Gout.—After Gudzent had observed a patient with gout, who had severe attacks every time he took milk treatment but who tolerated meat well, he

studied a larger material and reached the conclusion that the acute attack of gout has no connection with acute deposits of uric acid but is rather an allergic reaction to a gout toxin. He observed also a number of patients with rheumatism, who stated spontaneously that they always felt worse after taking fish, eggs or milk. Skin tests with these substances resulted in wheal formation, and abstinence from these foods produced considerable improvement. Further studies on this problem led him to the following conclusion. Rheumatic processes in the joints, muscles, nerves, tendons and blood vessels are the manifestation of a hyperergic reaction resulting from a hereditary or acquired hypersensitivity to a foreign protein. This protein may come from food, fermented drinks, pathogenic or non-pathogenic micro-organisms, mold fungi, yeast fungi or other substances. He made tests with various types of protein on 300 patients with rheumatic disorders and obtained positive reactions in 279 cases, 34 per cent showing a positive reaction to cereal proteins, 29.7 per cent to meat or fish proteins, 16.7 per cent to vegetable proteins, 9 per cent to bacterial proteins, 7.6 per cent to proteins from milk or eggs and 2 per cent to mold or yeast fungi. In patients in whom the test disclosed a sensitivity for a food protein, the author tried to eliminate the offensive substance from the diet, and a change of residence was prescribed for patients with a hypersensitivity to mold fungi. He admits that rheumatism and gout, after they have once developed, may be prolonged by secondary factors, such as cold, dampness, trauma, change in the weather and psychic factors, even if the primary cause has been eliminated. For this reason he attempted desensitization by means of intra-gluteal injection of the offensive allergen. At first the injections were given two or three times each week, then twice and finally only once a week. The entire treatment required from six to twelve weeks and more. He observed that the size of the dose does not determine the curative effect, and he commenced with small doses gradually increased to 1 and 2 cc. in order to avoid severe reactions. Because the condition was rather severe in the patients in whom this treatment was employed, he did not expect complete recovery but hoped to counteract the pains and swellings and to reestablish at least partly the working capacity. He was able to realize these aims in a satisfactory manner.

- Blood Fat Reactions in Endogenic Emaciation. G. Borruso—p. 783

Iodometric Studies on Human Urine.—Ruziczka shows that, in analyzing human urine with the rapid method of determination of the iodine number according to Margosches, Hinner and Friedmann, the values obtained are higher (iodine number I) than in case of direct titration with solution of iodine in potassium iodide, as prescribed by Lieb and Lanyar for the determination of homogentisic acid (iodine number II). Uric acid shows, in a 0.1 per cent solution, under conditions that obtain in the rapid method, even a higher iodine number than that which corresponds to the adding on of a molecule of hypouric acid. Accordingly, the carbonyl groups of the uric acid molecule do not act sterically to inhibit the saturation of the double linking. Thus the iodine number expresses also the uric acid content of the urine. If the iodometric acid determination according to the modification of Kolthoff is used, the urine always shows lower values than is the case in acidimetric titration and there is in this case no uniform relationship to the hydrogen ion concentration. These lower values are chiefly the result of the fact that an iodine consumption takes place under these conditions. That this is so is proved by the fact that, by the addition of the iodometric acidity and the iodine number II, a value is obtained that approximately tallies with the acidimetrically determined acidity. There is no regular proportionality between the iodometric acid number and the

"saponification number" To be sure, in many cases, such as in the urine of patients with diabetes mellitus, the terminal point in titration with hydrochloric acid is hardly detectable

Cholesterol Content of Serum in Skin Diseases—Hruszek describes experiments conducted to determine whether the serum of healthy persons and of persons with skin diseases, particularly psoriasis, has the capacity to dissolve cholesterol in vitro The same tests were made also on the serums of persons who had been subjected to a cholesterol tolerance test The author observed that some serums dissolve a portion of the cholesterol that has been added in vitro, these serums show positive lysis values Other serums do not change their cholesterol content following the lysis experiment, their lysis value is zero A third group of serums shows, following the completion of the in vitro test, lower values than before, which makes the lysis value of these serums negative These three types of serums are found in normal persons as well as in those with skin diseases, so that the cholesterolytic capacity is no indicator of the one or the other skin disease Patients with psoriasis may have any of the three types of serum, whether they have been subjected to a cholesterol test or not The author concludes from this that the cholesterol values of the serum are no indicators of the existence of a lipoidosis in psoriasis as was suggested by Grutz and Bürger He thinks that the pathogenesis of psoriasis is still unsolved

*Hepatic Function and Suitability for Surgical Treatment W König—p 863

Clinical Aspects and Therapy of Chronic Digestive Weakness During Childhood (Heubner Herter's Disease) E Holzmänn—p 864

Spongiosa Implantation in Fractures and Pseudarthroses—König says that Matti in 1929 suggested that in a pseudarthrotic tibia the medullary cavity be opened at the site of fracture, after the periosteum has been pushed aside, then the connective tissue that has formed between the fractured ends is removed except at the posterior wall, where the fibrous connection is preserved Then the femur is opened, through a longitudinal incision, below the greater trochanter by a periosteum-bone flap down to the spongiosa Material from the spongiosa is withdrawn and is introduced like mortar into the tibial cavity and between the freshened ends of the pseudarthrosis The periosteum is closed and the skin sutured The bone cover is replaced on the femur and the skin is closed König employed this procedure in four cases In one of these cases a local infection set in and the method failed, but in the three others the procedure was successful The author describes these three cases and reaches the conclusion that Matti's transplantation of the spongiosa is a simple method that can be employed with good success in bone fractures of the diaphysis that do not heal, as well as in pseudarthrosis

Hepatic Function and Surgical Treatment—König believes that in surgical operations failures are often the result of impairments of the liver that were not recognized before the operation. The significance of this problem goes beyond the scope of the surgical interventions on the liver or the biliary tract, for the function of the liver becomes impaired as the result of the anesthesia, the operation and the fasting period that usually follows He deplors that most of the functional tests of the liver are too complicated for the surgeon and stresses the necessity of simple tests He concedes that the urobilin and urobilinogen tests are helpful but considers them insufficient He accepts Mancke's suggestion, according to which Millon's test of the urine is helpful in estimating the hepatic function. His own experiences with Millon's test convinced him that patients in whom the test is positive before the operation are in danger If such patients absolutely require an operation, attempts should be made to improve the hepatic function before the intervention by medication with insulin and dextrose.

Compression Treatment of Phlebitis—According to Friedländer, thrombus formation in the venous circulation is one of the most difficult problems in medicine. He points out that it was Fischer who first advised that inflammations in thrombophlebitis be counteracted by compression and that the danger of embolism be averted by exercising the inflamed extremity Fischer's mode of treatment made it possible for the patients to get up and follow their occupation as soon as the compression bandage had been properly applied with a paste consisting of zinc oxide, gelatin, glycerin and water It is the aim of the compression bandage to reestablish the disordered circulation, to counterbalance the internal inflammatory pressure by pressure from the outside and to force the thrombus in its entire length against the venous wall. The author emphasizes that the pressure must be carefully adjusted to the individual needs, and he describes various ways of applying the compression bandage He calls attention to the difficulties encountered in the diagnosis of a thrombophlebitis He concedes that in the subcutaneous vessels the condition is usually readily recognized, but even in such cases erroneous diagnoses are possible Rheumatic pains in muscles and sciatika may lead to diagnostic mistakes in the deeper thromboses. A thorough internal examination is of vital importance. The condition of the heart must be known in order to regulate the circulation properly Urinalysis may disclose cystitis, cystopyelitis or diabetes mellitus The latter condition particularly may influence the course of thrombophlebitis A former syphilitic infection and the average alcohol consumption may be important as may also foci of infection. The condition of the lungs should be known, and the family anamnesis should give attention to such conditions as varicose veins, leg ulcers and phlebitis The author advises that the compression treatment be instituted as early as possible. The duration of the treatment differs As a rule it requires from four to eight weeks, but the patient may follow his occupation during this time. The patient should not use crutches or other supports. The author employed the compression bandage in 196 cases and observed only one fatal embolism, in a woman with pelvic thrombosis He did not observe a single fatality among the patients with thrombosis of the leg or thigh who were subjected to compression treatment

Pleximeter in Mechanism of Percussion—Winkler analyzes the factors involved in percussion and shows the shortcomings of the hitherto accepted theories about the part played by the pleximeter and by the thoracic wall The efficacy of percussion as a comparative and demarcating method of examination is determined by the diameter that goes through the entire depth of the normal lung The optimum of percussion is obtained when weak blows with light elastic hammers hit lightly applied, stationary, small-surface, readily flexible pleximeters or unilaterally movable, large-surface, elastic pleximeters The percussion sound of the lung is a sound mixture, in which the tissue sound of the axial penetration zone is the less masked by the other sound components, the more the axial mechanical blow effect approaches the optimal Every change in the percussion capacity of the pulmonary tissues within the axial penetration zone influences the character of the sound. The pleximeter makes possible a uniformity of factors by obviating differences in the time, surface and power of the blows and thus is a great aid in the practical utilization of percussion as a demarcating and comparative method of examination.

Zeitschrift für klinische Medizin, Berlin

- Relations Between Internal and External Secretion of Pancreas Herxheimer Mansfield Phenomenon in Pancreolithiasis E. Friedlander —p 184

Galactose Assimilation in Patients with Diabetes Mellitus—Schrumph observed, following galactose tolerance tests (40 Gm. of galactose) on eleven patients with diabetes mellitus, that the blood sugar content is higher. This increase is observable after one hour in the cutaneous as well as in the venous blood. The residual reduction in the blood shows after one hour a moderate increase, which is an indication of a rise in the galactose content. This gain is noticeable in the cutaneous as well as in venous blood, however, in respect to quantity it is less than the total increase in the blood sugar. It appears that the galactose, which is demonstrable in the blood of patients with diabetes mellitus, is not retained in the peripheral tissues. The urine contained galactose in only three out of eleven patients, and the quantities were so small that in view of the ordinary clinical evaluation of tolerance tests they cannot be considered pathologic. The galactose tolerance test was followed by noticeable glycosuria in only two patients, and in these the diet had not had the proper caloric composition. It appears that patients with diabetes mellitus can assimilate small amounts of galactose. The author thinks that the results he obtained in these studies indicate that galactose can be used more extensively in diabetes mellitus.

Biliary Pigment in Blood in Cardiac Decompensation.—Milovanovic and Stanojevic call attention to the fact that cardiac decompensation influences the hepatic function. In severe cardiac decompensation there often exists a slight jaundice, and many investigators agree that jaundice indicates an unfavorable prognosis in patients with cardiac decompensation. The publication of methods for the determination of biliary pigment in the blood has revived interest in the question of bilirubinemia in patients with heart disease, for these methods make it possible to detect a latent jaundice. The author reviews the literature on bilirubinemia in heart disease and then describes his own studies. He emphasizes that it is necessary to determine the bilirubin content of the serum and the function of the cardiovascular apparatus simultaneously. He determined the hydrodynamic condition of the cardiovascular system by means of the constant of Pachon and Fabre and the biliary pigments by the method of Hijmans van den Bergh. He reaches the conclusion that the prognosis is unfavorable in cases in which the constant is low, as well as in cases in which the constant decreases while the bilirubinemia rises.

- Pubiotomy Case A. Niedermeyer —p 1352

Elimination of Thyrotropic Substance in Urine of Menopausal Women.—Grumbrecht points out that the anterior lobe of the hypophysis secretes in addition to the growth and sex hormones, a substance that stimulates the thyroid to greater activity. Whereas the mode of action of the thyrotropic hormone is well known, its mode of elimination is not so well understood as yet. Accordingly the author decided to test the urine of menopausal women for the presence of the substance, because the symptoms that appear in menopausal women (rushing of blood to the head sweating and palpitation of the heart) are all symptoms indicating increased thyroid activity. An extract was prepared from the urine of these

women and was injected into infantile rabbits, which promptly developed accelerated heart action and other symptoms. Some of the animals died, the others were killed on the third day. The thyroids of the animals were subjected to histologic examination, which revealed changes indicating increased functional activity. The urine of the women who were in the early or late stages of the menopause produced less severe changes. The urine eliminated during the menstrual period likewise seemed to contain thyrotropic substance, while the urine of sexually mature women outside the menstrual period did not produce changes in the thyroid of the animals. The author concludes from these observations that the menopausal disturbances are the result of overfunctioning of the anterior lobe of the hypophysis, which is induced by the abolishment of the gonadal function. The treatment should attempt to reduce the thyrotropic action. This can be accomplished by the administration of iodine or of estrogenic substance. The author recommends di-iodotyrosin (35 di-iodo-4-oxyphenylalanine) either alone or in combination with the estrogenic preparations for the treatment of menopausal disorders.

- *Late Results of Tendon Transplantation for Flaccid Paralysis of Lower Extremities B. V. Rubinshtein —p 67

Parathyroids in Chronic Rheumatic Polyarthritides—Shkurov and Elenevskiy examined ninety-one histologic preparations of parathyroid tissue removed for therapeutic purposes from seventy-seven patients, thirty of whom were suffering from chronic rheumatic polyarthritides and forty-seven from spondylo-arthritis. The presence of parathyroid tissue in the removed material was established in each instance by histologic examination. The size of the glands removed did not exceed that given by most authors for the normal gland. On the basis of their observations the authors suggest that the secretory reaction is in all probability not limited to the chief cells and that the oxyphil cells likewise have a secretory function. They found oxyphil cells singly and in islets in fifty-three preparations, cells representing a transitional stage from the chief to the oxyphil type in thirty-four and a colloid-like substance in thirty-two. Clinically the cases presented increased blood calcium content, stiffness and ankylosis of the joints. The pre-operative blood calcium was above normal in twenty-two (up to 16 mg.), normal in eleven and below normal in only two. The twenty-two patients with hypercalcemia showed, after parathyroidectomy, an average diminution of 3 mg. per hundred cubic centimeters of blood serum. The clinical results were gratifying. Of the eighty-one patients submitted to partial parathyroidectomy, only three did not show any improvement, and in two the progress of the morbid condition was not arrested. The authors conclude that the oxyphil cells signify an increased function of the parathyroid and that chronic rheumatic polyarthritides and spondylo-arthritis are caused by hyperactivity of the parathyroid glands.

Results of Tendon Transplantation for Flaccid Paralysis—Rubinshtein reports the late results of tendon transplantation for flaccid paralysis of the lower extremities performed by Vreden in the Central Traumatologic Institute. The duration of observation was from one to twenty-one years. The patients were operated on from one and one-half to twenty-five years after the onset of paralysis. In their experience, good results could not be expected if patients were operated on earlier than three years after the onset of the paralysis. The controversial points among orthopedic surgeons with regard to operative indications center about the age of the patient and the duration of the paralytic state. The author feels that the most important element in the success of the operation is the correct evaluation of the strength and synergistic capacity of the muscle to be used as a substitute. He found Hübscher's table of relative strengths of the nine main muscles of the foot fairly reliable. While preservation of the sheath of the tendon is of great theoretical importance for the survival of the trans-

planted tendon, it was not done once in their work because of technical difficulties. Of the 238 operations performed on 215 patients, good results were noted after 220, satisfactory after twelve and poor after six. Advantages of tendon implantation under an osteoperiosteal bridge are emphasized.

- *Simple and Sensitive Test for Bilirubin in Urine A. W. J. H. Hoitink —p 2928

Positive Venous Pulse—Formijne studied the venous pulse of four patients in whom there was simultaneous contraction of the auricle and the ventricle. One patient showed a strongly positive venous pulse due to marked delay in the conduction time. Another had a 2:1 auriculoventricular block. The blocked P wave occurred simultaneously with the contraction of the ventricle. The venous pulse was weakly positive. A third patient showed nodal rhythm and a positive venous pulse. The last patient had a history of nodal rhythm with a negative venous pulse. One year later she developed an arrhythmia in which the P wave occurred at the same time as the ventricular contraction. A synchronism of the auricular and ventricular systole resulted. These cases indicate (1) that a positive venous pulse may appear if the auricular contraction through some mechanism accompanies the ventricular systole, but that (2) the intensity of the positive venous pulse may vary greatly or may be absent. In order to explain these differences the author investigated the expansion and contraction of the right auricle, of the junction of the vena cava superior and the right auricle, and of the large vessels. A varying degree of competence of the valvular mechanism at the junction of the vena cava superior and the right auricle is advanced as a possible explanation of the positive reaction. The contractile power of the auricle may play a part in the causation or failure of the venous pulse. To illustrate the importance of the condition of the large veins the author presents a patient in whom a unilateral left positive venous pulse was found, which he ascribed to a tricuspid incompetence associated with the presence of a left vena cava superior.

Test for Bilirubin in Urine—Hoitink experimented with a modification of Fouchet's test for bilirubin in the urine. The following technic was used. About 10 cc. of urine is put in a test tube. If the reaction is not weakly acid, it is made so by means of acetic or hydrochloric acid. Half the volume of the urine (5 cc.) of a 10 per cent solution of barium chloride is added. The contents of the tube are mixed well and filtered. The filter paper with the precipitate is spread on a ground glass slide or on another piece of white filter paper. One drop of Fouchet's reagent is applied to three different places on the border of the precipitate. After five minutes a blue or greenish color indicates bilirubin. The author detected 0.05 mg of bilirubin per liter of urine. He found the test more sensitive and simpler than the Gmelin, Huppert-Salkowski-Steensma and other tests.

- Coxa Vara Infantum Case C. Johannessen —p 493
- Ruptured Mesenteric Chyle Cyst Two Cases L. E. Volodarsky —p 496

Tuberculosis of Heart and Great Arteries—Dahl reviews the subject, citing cases, and reports three instances. While the cases of chronic tuberculous changes found by him in the literature were localized particularly in the aorta, in his patient, a girl aged 10 years, presenting acute miliary tuberculosis, there was an infiltration 2 cm. long, 4 mm. wide at the widest point and extending 3 mm. into the lumen, in the left pulmonary artery. Microscopic examination disclosed a true conglomerate tubercle, entirely localized in the intima. From the size and

the marked cheesy necrosis of the infiltrate, in contrast to the apparently recent miliary tubercles in the various organs, and from the beginning invasion of the media, he regards this as an older process, originated by direct infection through the blood stream and as the starting point of the miliary tuberculosis. The primary focus was not discovered. In the second patient, a woman aged 29, the hematogenous metastases could be localized in the valves of the heart. A tubercle, larger than the head of a pin, was found in the anterior mitral valve. The infiltration, situated under the elastic membrane of the valve endocardium, presented a marked cheesy necrosis, surrounded by typical granulation tissue with giant cells, and had invaded the adjacent valve endocardium. Abundant tubercle bacilli were found. In the third patient, a man aged 70, with cancer of the stomach and no signs of heart disorder or circulatory disturbance, the apex of the left lung was the seat of two inveterate, partly calcified infiltrations the size of a pea. On the wall of the left ventricle was a round, well defined tumor the size of half a walnut, firm and smooth, and in the ventricle, corresponding to the tumor, was a layer of thrombus masses. Microscopically the tumor consisted of a homogeneous, structureless mass surrounded by granulation tissue without special characteristics, continuing directly into the thrombus stratum. Tubercle bacilli were present in great numbers. The process is assumed to have originated by hematogenous infection from the older lung disturbance in the left apex. The heart was of usual size, without hypertrophy of the musculature of the left ventricle.

- *Acute Myocarditis in Nonseptic Gonorrhea G. Guldberg —p 576
- Erysipeloid R. Ström —p 581
- Frequency and Localization of Arthritis Deformans Among Lapps. A. E. Schreiner —p 592
- Tuberculosis Mortality and Tuberculosis Morbidity K. F. Andvord —p 599

Blood Sugar and Liver Function in Skin Diseases—Guldberg and Hannisdal's material comprises sixty-four cases in which five of the patients (two with exfoliative dermatitis, two with chronic eczema and one with mercury dermatitis), in addition to low fasting blood sugar, had marked posthyperglycemic hypoglycemia, the values falling as low as 29 mg per hundred cubic centimeters without certain signs of hypoglycemic reaction. In four of the patients, treatment with dextrose injected intravenously together with insulin was promptly effective.

Acute Myocarditis in Nonseptic Gonorrhea—Guldberg's case shows that, in a person with gonorrheal urethritis and prostatitis with afebrile and wholly favorable course and without clinical or bacteriologic signs of general infection, grave cardiac complications may occur in the form of acute myocarditis, which in this instance set in after three weeks. The electrocardiogram revealed a partial atrioventricular block and did not become normal until four months had passed.

Supplement 1 79 (June) 1935

- *Dyspeptics Contribution to Pathology of Some Chronic Gastro-Intestinal Disorders Especially on Basis of Clinical Observations on Functional Relations in Vegetative System in One Hundred Patients Having Digestive Disorders M. S. Kober —p 1

Pathology of Chronic Gastro-Intestinal Disorders—Kober's cases, all in adults, represent chronic unspecific disorders of the digestive tract without complicating disturbances. No definite physical type, he says, is characteristic of patients with dyspepsia, although 50 per cent of the patients were leptosomatic. Extensive indications of a vegetative neurosis were seen in all cases, apparently with a vagotonic predominance. He concludes that there is a close relationship in all digestive disorders and between these and the vegetative neurosis, which he assumes to be primary. Chronic dyspepsia is a forerunner of gastric ulcer. The vegetative neurosis is the expression of a toxic condition of the organs. The unknown toxin acts in two ways, producing a vegetative lability and a toxic gastritis, these together cause the erosions and thus the ulcer. Constipation, colitis, so called primary chronic appendicitis, different phases of chronic dyspepsia, gastritis and peptic ulcers are different stages and different anatomic localizations of one and the same pathologic condition.

OBSERVATIONS ON THE TREATMENT OF ACNE VULGARIS

CHAIRMAN'S ADDRESS

JEFFREY C MICHAEL M D
HOUSTON, TEXAS

Most of us are probably agreed that the therapeutic problem of acne is not yet satisfactorily solved. The early favorable results with roentgen therapy and especially the wider use of this modality following the more exact dosage obtainable with the Coolidge tube made it seem for some years that little more was needed, but a later appraisal of the results seems to have shown that there is still room for improvement. This realization together with the more recent knowledge of female hormone physiology and therapy has led to a renewed interest in the therapeutic problem of the disease. At present there is a state of flux concerning it. Formerly the treatment was practically routinized, the routine being so many doses of the roentgen ray. Now there is a greater tendency to recognize the limitations of the therapeutic weapons and to individualize and select treatment according to each case. To me this seems to be a step forward and one that should be encouraged. For that reason the present topic especially appealed to me, for it is only with a knowledge of what the present situation is that the weak points can be eliminated. With these thoughts in mind I feel that an analysis of the present therapy of the disease, the recent studies made in this field and those touching on it, together with some personal opinions about some of the more important phases of the subject will be of interest.

ETIOLOGY

A proper approach to the treatment of patients with acne demands a consideration of the etiology of the condition. This is necessary because the disorder is a syndrome rather than a disease *suu generis*. There are a few investigators who apparently regard acne vulgaris as essentially a local infectious disease of the skin based on a primary seborrhea (Sabouraud¹), but most dermatologists apparently agree with Kyrle,² Mumford³ and others that acne vulgaris is a syndrome in which the influence of one factor, or more likely a number of contributing factors, is of fundamental importance. The proponents of a primary local bacterial causation, despite a great deal of investigation, have still failed to

prove their case. Ketron's⁴ more recent investigations of *Bacillus acnes* as an etiologic agent led him to hesitate to ascribe any definite role to that organism in the etiology of the disease. Even in regard to the pustular element in acne, there is not at the present time absolute unanimity of opinion. Of course, most dermatologists attribute suppuration in the lesions to the staphylococcus, nevertheless there is not complete agreement about this feature of the disease, as is evidenced by the recently repeated assertion of Sabouraud¹ that the staphylococcus is not responsible for the pyogenic element in the lesions of acne. This naturally leads to the statement that the entire question should be reinvestigated, since it has a practical bearing on the therapy of the disease.

The second approach to an elucidation of the pathogenesis of the disease, namely, to regard it as a syndrome, is more in favor. Thus far it has led to nothing tangible, at the most to rather vague generalizations. Needless to say, clinical observation tends to indicate that certain internal factors, such as the physiologic and pathologic activities of the endocrine system and various minor disorders such as anemia, constipation and foci of infection, play a more or less important role in the production of the disease. Whitfield⁵ recently discussed these factors and especially emphasized the importance of gastro-intestinal disturbances.

While recognizing the tremendous influence of sexual ripening on the incidence of acne, the dermatologist is still at a loss to explain why acne affects certain adolescents and spares others. Even more elusive apparently is the causation of the acne of adult life in which the hormone factor is not so much in the foreground. In short, while clinical observation has taught a great deal about the disease and its behavior, an elucidation of the pathogenesis of the disorder is still lacking. A better insight into the etiology of the disease is, of course, highly desired since the condition is of enormous practical importance.

The primary lesion of acne is the comedo. This is the first appreciable clinical manifestation of the disease. Why does a comedo form? The generally held conception of its formation is that of a mechanical blocking of the follicle by a hyperplasia of the epidermis at its mouth leading to a retention of sebum with an intermixture of horny cells from the follicular wall. Whatever the cause of the follicular hyperkeratosis, there can be hardly any doubt as to the primary role of this hyperplasia since histopathologic examinations (Unna,⁶ Kyrle²) confirm it.

Read before the Section on Dermatology and Syphilology at the Eighty-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., June 12, 1935.

This hyperplasia occurs as a physiologic process during puberty, being part of the activation of the pilosebaceous apparatus by the gonadal stimuli of that period. It may also appear as a pathologic response to exogenous irritation (oil, wax, tar or paraffin) producing the disorder known as oil acne. Accompanying this hyperkeratosis of the follicular ostium there may be and usually is an increased sebaceous secretion, especially in cases of acne vulgaris, but this does not always occur and it is not necessary in the production of comedones. As is well known, a patient with acne vulgaris is occasionally seen whose skin is dry rather than seborrheic. At any rate, once the comedo is formed, there is only required the element of follicular inflammation to produce the clinical picture of acne. The difficulty, of course, arises as to the explanation of the development of comedones (and acne) in one adolescent and not in another since all are presumably under the same gonadal influence and show fairly uniform responses of the pilosebaceous apparatus in other directions (pubic, axillary and male beard hairs). Kyrle² expressed the belief that two possible explanations were conceivable, namely, an abnormal response of the pilosebaceous system in some subjects to the same stimuli, or in some cases an abnormal supply of hormone or other stimulus. Sulzberger, Rostenberg Jr and Sher⁷ followed the same line of reasoning. In a preliminary way they endeavored to ascertain whether there is a follicular hypersusceptibility to one or more of the possible irritants. Their preliminary investigations showed negative results but of course do not invalidate or weaken the hypothesis. Stein⁸ advanced the hypothesis that acne vulgaris is caused by an irritation of the follicular wall by the elimination of metabolic products of the gonads and of substances absorbed from the intestinal tract. He quoted Blaschko as seeing the analogy in this process between true acne and acne artificialis caused by bromides.

In regard to the fundamental change, namely, the hyperkeratosis and epidermal hyperplasia that underly the formation of comedones, an interesting and perhaps significant chemical interplay comes to mind. In the experimental production of cancer use is made of tar or tar fractions (carcinogenic compounds) which when rubbed on the skin of a laboratory animal regularly produce cancer in a certain length of time. These substances operate by producing epidermal hyperplasia. Similarly, the acnes caused by greases, tar and oil that reach the skin from without (occupational oil acnes) are apparently produced by the primary irritation of the follicular ostium and wall. The carcinogenic compounds are known to have a phenanthrene nucleus and this substance is also present in coal tar and many greases. It is striking that the phenanthrene nucleus is found in both the male and the female sex hormones, which are closely related chemically (Dodds⁹). It seems more than a coincidence that the phenanthrene nucleus should be so closely connected with pilosebaceous hyperplasia and irritation. This thought may serve a useful purpose in further investigations on the pathogenesis of acne vulgaris.

The approach to the elucidation of the causation of acne by clinical studies has produced some interesting

observations, but unfortunately nothing that can be said to represent a fundamental advance.

Among these newer contributions the investigation of the late Bruno Bloch¹⁰ revealed the great frequency of acne. Bloch and his collaborators examined 4,191 school children between the ages of 6 and 19 (about equally divided as to sex) for the presence of acne vulgaris. Various degrees of the disorder, from a few comedones to true acne with papules and pustules, were tabulated. Their investigation showed that approximately 64 per cent of the children were affected with at least a few comedones. Of true cases (severe enough to be considered a disease) there were 8 per cent among females and 20 per cent among males. The preponderance of males in all the degrees of the disorder was definite and may have some pathogenic significance (Sulzberger, Rostenberg Jr and Sher).

Without going into further details in regard to Bloch's observations it may be said that the well known observation of the chronological relation of acne and puberty was substantiated. So frequent was some manifestation of acne found among these adolescents that Bloch concluded that the disorder must be based on a physiologic condition, and that it is unnecessary to invoke a pathologic substratum for the disease. In short, Bloch concluded that those elements that are almost taken for granted as important contributory factors in cases of acne, namely, constipation, anemia and menstrual disorders, are certainly not responsible for the disease among juveniles (his researches did not include acne of adult life). Apparently alone among earlier writers, Pollitzer¹¹ stated this same belief on the basis of his clinical observations.

In this country the study of Cunningham and Lunsford¹² deserves particular comment since it comprised an older group of subjects (women college students) than Bloch's. These investigators compared 2,974 young women with acne with 3,185 control students with regard to the incidence of constipation, colds and other infections, and the condition of the thyroid gland, nose and tonsils, as well as the menstrual history. There was practically no difference between the two groups in respect to the incidence of these systemic disorders to which a contributory influence on acne is so uniformly ascribed. The conclusion to be drawn from this study is that these disorders apparently have little or no influence on the incidence of the disease. But for the present, judgment on this conclusion must be reserved since the question of an inherited predisposition obtrudes itself and cannot be definitely evaluated, though it is probably of some moment (Siemens,¹³ Stokes and King¹⁴).

As has happened so often before, biochemical studies have given no further insight into the pathogenesis of the disease. Greenbaum's¹⁵ investigations of tolerance to dextrose led to nothing significant, and Strickler and Adams'¹⁶ somewhat different approach to the question

of sugar metabolism in cases of acne led them to deny any influence of sugar metabolism on the disease. The same authors¹⁷ found no etiologic indications in the cholesterol metabolism of patients with acne. Knowles and Decker¹⁸ and recently Immerman¹⁹ sought to throw light on the etiology of the disease by means of gastric analysis but found nothing of significance.

Ramel's²⁰ investigation of the deep nodular form of acne vulgaris led him to the conclusion that this type is of tuberculous origin. This will hardly be accepted without further corroborative evidence, which, at most, was only partly given by von Kerner's²¹ report of the therapeutic benefit derived from the removal of foci of infection and subsequent tuberculin treatment. Of fifty-two patients twenty-two recovered after the removal of pyogenic foci, and all but three eventually were cured after subsequent tuberculin therapy.

INFLUENCE OF ENDOCRINE DISTURBANCES

Of especial interest at present are the recent studies of female hormone disturbances associated with acne vulgaris in which the newer methods of detecting the presence and amount of these substances in the urine has been employed.

Deseau and Guillaumin²² used the interferometric method of Hirsch in a small series of patients selected because an endocrinopathy seemed to be a factor. The results confirmed this surmise as in each case an endocrine disturbance was indicated by the test. Measures taken to combat the disorders led to beneficial therapeutic results.

In this country Rosenthal and Kurzrok²³ appear to be the only investigators who have attempted a clarification of the problem of acne by hormone titration. They determined the presence of estrogenic substance in the urine of thirty-four patients with acne. Though estrogenic substance is normally found in the urine during the active sex life of all women, it was absent in twenty-seven of the patients, in normal quantity in six and in small quantity in one.

Along the same line is an interesting and optimistic report by von Leszczynski and Liebhart²⁴ on the therapeutic results obtained in cases of acne when based on hormone tests. These authors expressed the belief that acne may rest on a physiologic basis in early years (Bloch) but that acne in early adult life and later years is the result of a pathologic condition. Their patients were studied carefully for systemic disturbances, and tests for hormone function and presence were carried out as thoroughly as possible. For the determinations of estrogenic substance and the anterior pituitary-like principle from the urine of pregnancy, Zondek's methods were used. As a consequence of these studies they concluded that it is possible to divide patients with acne into three etiologic groups. This grouping is based partly on certain clinical characteristics of the

disease and partly on the results of endocrine and general studies. So-called pure types of cases are not common. The three types of acne are as follows:

1 *Acne Sexualis*—In pure cases it is limited to the face, especially the cheeks and chin. Seborrhea is slight or absent. Menstrual disturbances are usually present and exacerbation of the acne nearly always occurs during menstruation.

2 *Acne Intestinalis*—This type has a predilection for the trunk. A seborrheic condition usually in moderate degree is nearly always present. Constipation of the atonic type, visceroptosis and colitis are frequent. These cases are based on intestinal stasis.

3 *Acne Thyreogenes et Seborrheica*—This is a severe type in which large papulopustules as a rule affect all the usual regions. Kerosis is common. Enlargement and hyperactivity of the thyroid gland is frequently associated.

Identification of these types may require both clinical and detailed laboratory study. According to the authors recognition of these etiologic forms is absolutely requisite for the best therapeutic results. They did not use roentgen therapy but considered local applications to be important. The internalistic and endocrinologic outlook of these authors is stimulating. Their therapeutic results, contained in a report of fifteen patients, were apparently excellent.

Recently Van Studdiford²⁵ reported some interesting therapeutic results based on opotherapy.

For some time in selected patients I have made an attempt to utilize the newer knowledge of female hormonology in the therapy of acne vulgaris. In years past the crude extracts then available were occasionally employed but without any encouraging results. Since the availability of the newer endocrine products, I have worked in cooperation with gynecologists in an endeavor to employ these preparations in the most exact manner possible. The selection of suitable patients has been first made by me and the selection of hormone therapy by the gynecologist after a study of each patient from that special point of view. In this way twenty-six females have received what may be considered as reasonably good opotherapy. Up to the present the therapeutic results have been poor and discouraging so far as the influence of the hormone treatment on the acne is concerned. I have seen a number of instances of improvement or even complete relief of menstrual disturbances without corresponding benefit of the acne. It should be mentioned, however, that the studies of the individual case prior to the institution of glandular products in no way approached the thoroughness of von Leszczynski and Liebhart so that the type of therapy in some cases may have been ill chosen. My present opinion in regard to this phase of the therapy of acne is that theoretically it is enticing, but that practically, for the present, it is of slight value.

ULTRAVIOLET RAYS, VITAMINS AND BACTERIAL PRODUCTS

Butler²⁶ reported highly satisfactory results with ultraviolet rays. He did not give any figures but stated that relapses were frequent. Louste and Juster²⁷ likewise reported favorable effects with this method after

a year's experience Andrews²⁸ spoke favorably of it. A few physicians have used it conjointly with the roentgen ray, but this combination is not considered desirable by most dermatologists. Ultraviolet therapy has the great disadvantage of requiring a dose of some degree of erythema (sufficient to cause at least moderate desquamation) to produce favorable effects. For this reason I have used it in only a few instances in which the acne has been resistant to other measures and in these cases unsuccessfully.

On the whole, ultraviolet radiation plays a subordinate role in the therapy of patients with acne.

In a brief note Doktorsky and Platt²⁹ recorded definite clinical improvement in patients with pustular acne following the administration of vitamin D. My own experience with this preparation in eleven patients ranging in age from 14 to 22 years was not encouraging. My patients were all undergoing other forms of treatment at the same time but did not seem to respond any faster to this therapy than if vitamin D had not been administered.

Years ago, Fox³⁰ reported on the use of vaccine therapy and concluded that it was practically useless. This appears to be the generally accepted opinion at present, though an occasional patient with the pustular type of acne seems to respond to vaccine treatment. Staphylococcus toxoid, which was valuable in Dolman's³¹ hands, was unfavorably reported on by Kindel and Costello³² and Cornbleet and Rattner³³. Bacteriophage, though found to be of value by Blum and Peyre³⁴ and Alderson,³⁵ was ineffective in Crutchfield and Stout's³⁶ experience.

ROENTGEN THERAPY

As is so well known, for many years the roentgen ray has been the dermatologist's chief weapon in the attack on acne. The action, technique and dangers of this physical agent are too well known to require description here.

In the earliest report in this country (Pusey) the results achieved were extolled and there followed a series of articles confirming this pioneer's enthusiasm. With the development of the technique of exact dosage (MacKee³⁷, Witherbee and Remer³⁸), the roentgen ray became the trained dermatologist's most commonly used method. So enthusiastic were the earlier reports that for years there was a general impression that little more than a proper knowledge of the use of the roentgen ray was required for the successful therapy of patients with acne. Earlier reports and impressions were that from 90 to 95 per cent of the patients were permanently curable in about four months. The treatment became almost stereotyped and aside from more or less casual

directions about diet, routine correction of constipation and standard tonic regimen when obviously indicated, roentgen therapy was wholly depended on to produce satisfactory results.

Misgivings about this apparently successful therapeutic method led me³⁹ to investigate the end results obtained in a series of about 200 cases. This series, while too small to warrant the drawing of definite conclusions, showed trends which were obviously at variance with the commonly accepted belief of the efficacy of the roentgen ray. Since my report, those of Lord and Kemp⁴⁰ and of MacKee and Ball⁴¹ have appeared and have confirmed what was indicated in my personal experience. In the main, these three reports agree. Lord and Kemp, however, did not, like myself, find that recurrences in the period of puberty and the immediately following years were so frequent. MacKee and Ball, however, confirmed my observations on that point. The figure for recurrences in patients up to 18 years of age found by me was 47 per cent after the first course of treatment, and after the second course (maximal permissible roentgen therapy) was 22 per cent. Thus, approximately half of the patients had a relapse and in one fifth there was ultimate failure. Of the patients up to 25 years of age, 35 per cent had a relapse after the first series of treatments and 12 per cent after an additional series. MacKee and Ball did not report their recurrences by age groups but stated that relapses were frequent among the younger patients.

Despite this frequency of relapse, it should be stated that the roentgen ray is a dependable agent and is curative in a vast majority of the cases of acne, the final successes approximating 80 per cent. It can be depended on to clear up the lesions in practically all cases in a period of from three to five months. In principle, therefore, if the necessity arises to eradicate the lesions, the roentgen ray may be depended on to do so with a remarkable degree of certainty. Unfortunately, as previously noted, this certainty of temporary cure is not followed sufficiently often by permanent freedom to be entirely satisfactory.

COMMENT

From the foregoing observations it is obvious that the treatment of patients with acne cannot be stereotyped if the best results are to be obtained. The choice of the therapeutic attack is a matter of analysis of the individual case. For the purpose of this analysis the important questions to be taken into consideration are (1) the information obtained by a history and systemic examination (foci of infection, anemia, diet, gastrointestinal function), (2) the age of the patient, (3) the mildness or severity of the case and (4) the endocrine factor, if determinable.

As to the first group of contributory causes (anemia, constipation and so on), it goes without saying that they should be taken care of according to general medical principles. The dietary regimen deserves special mention since there is no unanimity regarding the importance of diet in the disease. Apparently some physicians neglect it completely. Urbach⁴² stated that there was no scientific evidence which indicated the type of diet

that should be effective in the disease Stokes⁴³ thought it of great importance and of valuable therapeutic assistance when carried out in the detail comparable to that in cases of diabetes. The type of diet best suited to the patient with acne is generally agreed on and need not be detailed. Every textbook contains a practically similar list of interdicted and permissible substances. In a former study I could not find that diet played any apparent role in the results obtained, yet it is unquestionable that in individual cases diet seems to be provocative of outbreaks and in some instances the breaking of dietary instructions has been followed by relapses in seemingly cured patients. White⁴⁴ reported a series of cases in which specific sensitivity to foods produced outbreaks of acneiform lesions. These cases should not be confused with those of true acne, since he expressly stated that comedones were not present.

The same line of thought applies to a focus of infection, its presence may render therapy unavailing in some instances, while in others it seems to have no influence on the course or response of the disease.

In regard to the mildness or severity of the case, the important point is whether or not scarring is being produced. In some of the mild cases (judged by number of lesions) each lesion produces a small pit that in the aggregate becomes of considerable concern to the patient. If, on the other hand, the disease is mild and not causing scarring of any moment, a campaign of local therapy and general measures can be followed with more equanimity by the patient and physician than if the lesions are numerous, unsightly and producing large permanent scars. Under the latter circumstances the therapy that promises to control the disease in the shortest possible time is indicated.

The age of the patient is one of the most important considerations in a choice of therapy. This personal opinion is based on the conviction (supported earlier in this paper by reference to recorded experience) that age is the most important element in the prognosis, especially when roentgen therapy is used. When that method of treatment is depended on for cure, about half the patients under 18 years of age have a relapse. Since the treatment consumes time and is somewhat expensive, the number of failures leads to considerable dissatisfaction. It has therefore been my practice for some time to withhold roentgen therapy from all patients under 18 years unless there has been absolute failure of response to other measures and marked scarring is being produced. In short, in juvenile cases of acne roentgen therapy is hardly ever used. It seems to me best to treat these patients persistently with local applications of a stimulating and astringent type and by all known measures of influencing the disease through the general system to keep the disorder at a minimum. Under such a regimen the patient must be apprised at the beginning of treatment that cure is not anticipated, that a long period (probably of several years' duration) of therapy is required and that only in the event that the disease is causing pronounced cosmetic difficulties will roentgen treatment be administered. The recent article by Nichols⁴⁵ demonstrated that such a method is attended by satisfactory results, to which I can testify from an extended experience. The success of this program is dependent in no small degree on the psychological influence of the physician.

On the other hand, in patients from 18 to 22 years of age irradiation is probably the method of choice. Relapses are less frequent than in the earlier age group and in instituting roentgen therapy one is in many cases but aiding and anticipating the natural tendency of the disease to disappear about this time of life. For this reason, I use irradiation practically as a routine measure for patients who are in this age group if the severity of the disease justifies it.

Patients in the middle twenties and older, however, present a somewhat different therapeutic problem. In many cases the disease has continued since adolescence, in others it begins in this relatively late period. Among the former are many cases in which the endocrinal upset initiated by puberty has not been adjusted normally, while in others, systemic disturbances (pelvic disease, gastro-intestinal disorders) appear to be primary etiologic factors. Proper management in this group must comprise an industrious search and eradication, if possible, of all suspicious contributing factors. Among these patients, in my experience, are found a large number that fall into the intestinal type of von Leszczynski and Liebhart. Radiation therapy apparently is more helpful to these patients than to the younger ones. It is a poor policy, however, to depend on it rather than to make a diligent effort to ferret out and attack the many possible and important contributing causes.

CONCLUSIONS

1 Acne vulgaris is a syndrome the cause of which is a complex of various interacting factors. In juvenile patients the physiologic activity of the gonads appears to be the most important factor. In older patients minor functional and organic disorders apparently (but not indisputably) play a definite role in the causation.

2 The recent tendency to depend less on roentgen therapy and more on general and local measures should be encouraged. While the roentgen ray is the most certain means of eradication of the lesions, recurrences are too frequent to make this treatment entirely satisfactory.

3 In juvenile patients recurrences are especially frequent and for this reason it is believed that the roentgen ray should not be used except under unusual circumstances.

4 For older patients, especially those between 18 and 25, roentgen therapy is the method of choice. It should be supported by an industrious search for and attention to any probable etiologic factors.

1017 Medical Arts Building

Incomplete Proteins—In order that food proteins may be transformed into the proteins of body tissue, they must first be resolved in the digestive tract into their component amino acids. It is in the form of their amino acids that the food proteins are absorbed from the digestive tract and distributed to the various active tissues of the body, where they may be used as needed in new combinations characteristic of the species and of the particular tissue. Some of the amino acids are convertible into each other and so need not individually be furnished by the food proteins. But several individual amino acids contain characteristic chemical structures or groupings which the body cannot obtain from other sources nor manufacture for itself and so a food protein lacking in one or more of these "nutritionally essential" amino acids is, when taken by itself an incomplete protein from the nutritional point of view. Gelatin and one of the proteins of maize belong in this group—Sherman H. C. Food and Health, New York, Macmillan Company, 1934.

DINITROPHENOL IN THE TREATMENT
OF OBESITY

FINAL REPORT

M. L. TAINTER, MD
A. B. STOCKTON, MD
AND
W. C. CUTTING, MD
SAN FRANCISCO

Since our first report on the metabolic stimulant action of 2-4 dinitrophenol (alpha)¹ in animals and men, and a preliminary paper indicating clinical possibilities for this compound² its use has been continued in the outpatient department of the Stanford Clinics and in private practice. Some of the early clinical results in obesity were summarized in a progress report.³ Various clinical reports have detailed the actions of the drug under different dietary conditions,⁴ its circulatory effects,⁵ changes in blood cholesterol,⁶ and effects on the icteric index and van den Bergh test.⁷ The evidences for changes in blood cholesterol, liver damage and certain red blood cell characteristics were negative. Our experimental work and clinical experience with the drug has now extended over a period of four years, during which time it has been given to hundreds of patients. Therefore it is felt that there may be offered now definite conclusions as to its effects in the treatment of obesity and its value in the therapeutic armamentarium. The experimental results have been summarized in several previous publications⁸ and all but the most recent clinical data in a recent review.⁷ In this report we will refer only to those clinical articles not discussed in previous publications and those which bear directly on the questions discussed. Time and space will not permit a discussion of the numerous articles that have already appeared in many journals and languages.

PATIENTS STUDIED

The total number of patients studied was 177. All complained of excess weight. Seven of them were seen only once and could not be included in the series.

From the Departments of Pharmacology and of Medicine, Stanford University School of Medicine.
Read before the Section on Pharmacology and Therapeutics at the Eighty-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., June 13, 1935.

Supported in part by a grant from the Rockefeller Fluid Research Fund of the School of Medicine, and by Grant 320 from the Committee on Scientific Research of the American Medical Association.

This left 170, of whom twenty were men and 150 were women. Ninety-nine of the patients received no previous treatment, twenty-six had tried only diet, seventeen had taken only thyroid, and twenty-eight had taken both diet and thyroid. In addition, six patients had taken whole pituitary and ovarian substance by mouth. Those patients who had received previous treatment either had failed to lose weight on it or were showing no further losses at the time dinitrophenol was given. All the patients have been included in the average figures regardless of whether they were cooperative or not, or of the duration of treatment with dinitrophenol. They were not a selected group, aside from their obesity, and hence represented a cross-section of cases as seen in ordinary practice. We have attempted to show not the very best statistical results that might be obtained with dinitrophenol in selected patients but rather average effects, such as any practitioner might be able to duplicate.

DIETARY CONTROL

In order that a regimen for weight reduction may be effective, there must be some control of the diet, so as to avoid an excessive intake of food. Because of the special approach to the present problem, no attempt was made to control rigidly the diet of the patients when on dinitrophenol. Those who were already on a fixed diet were instructed to stay on that diet. The remainder

TABLE 1—Effect of Dinitrophenol on the Basal Metabolic Rate

Dose Gm	Number of Determinations	Average Metabolic Rate per Cent	Range per Cent
Control	37	+ 0.2	-27 to + 19
0.1	1	+18	
0.2	10	+20	- 6 to + 88
0.3	10	+31	+ 7 to + 66
0.4	16	+50	+22 to + 83
0.5	8	+66	+ 7 to +107

were instructed about the role of food intake in the production of obesity and requested to take no more food than they had been previously taking. However, no patient was required to adopt a fixed weighed diet of low calorie value. If this had been required, the losses in body weight would have been greater.

ADMINISTRATION OF DINITROPHENOL

The sodium salt of dinitrophenol has been used exclusively, except for a few months in the beginning of the studies. The drug was of the highest purity obtainable from commercial sources, but before use its purity was verified, and it was further purified by recrystallization if necessary. No product was used that did not melt sharply between 296 and 298 C. (uncorrected) and was not colorless in acid solution. In determining the melting point it was necessary to dry it first in a desiccator and to heat as rapidly as possible to 285 C. and then very slowly from that point on. An occasional sample would explode at a few degrees below the melting point. Control of the purity is important, since commercial samples of the drug of supposed highest purity have been found by us grossly contaminated and unsafe for medicinal use. It is conceivable that some of the untoward effects reported by others may have been caused by an impure or contaminated drug.

The drug was administered in capsules containing 0.1 Gm. of sodium dinitrophenol, taken with meals. In general, the dosage was started with 0.1 Gm. daily during the first week and then increased to 0.2 Gm. daily

After a period of several weeks, during which the symptomatic response and rate of weight loss were ascertained, the dose was increased in 0.1 Gm steps until either the symptoms or the loss of body weight indicated no further change in medication. It was attempted to keep the weekly rate of weight loss between 2 and 3 pounds (900 and 1,300 Gm).

More than 50,000 capsules have been administered in this study, or an average of about 300 capsules per

TABLE 2—Ratio Between Dosage and Rate of Loss of Body Weight

Dose Gm	Number of Patients	Total Number of Days	Average Number of Days per Patient	Total Weight Loss Pounds	Average Weight Loss Pounds per Patient Weekly
0.1	37	516	14	69	0.84
0.2	145	3,503	24	637	1.28
0.3	154	4,718	31	894	1.33

0.4	95	3,765	40	697	1.30
0.5	34	1,417	42	237	1.17
0.6	10	472	47	149	2.21
0.7	1	16	16	7	3.08
0.8	1	7	7	3	3.00

patient. The average duration of treatment for the entire series was eighty-eight days per patient, with an average dose of 3.4 capsules or 0.34 Gm daily. The longest period of treatment for any one patient was one year, and the highest dose taken was 0.8 Gm. The latter dose was taken by a physician on his own responsibility. The highest dose prescribed by us was 0.6 Gm and this only for short periods in patients previously medicated at lower dosage levels.

METABOLIC LEVELS

Unfortunately, the cost of basal metabolism determinations prevented us from following the metabolic rates continuously in all patients. However, a total of eighty-eight determinations was made, distributed over the various dosages so as to give reasonably reliable information on the degrees of metabolic stimulation produced.⁹ It can be seen from table 1 that the average increase in metabolic rate was roughly proportional to the dosage of the drug. There was on the average about an 11 per cent increase in the basal metabolic rate for each 0.1 Gm of the daily dose, although the variations in individual patients were rather wide. This difference in susceptibility makes it highly desirable to individualize the dosage and treatment according to the regimen already described. A factor that modified the absolute rises obtained was the use of the smallest dose that would cause the desired therapeutic response. As a result, the more sensitive patients were given only the lower doses, while the higher ones were administered only to resistant patients. Hence the metabolic rates in table 1 do not indicate the average responses that might be expected from the same doses given to an unselected group of patients. They indicate rather an average response considerably below the unselected one.

WEIGHT LOSS

Five patients treated for only short periods lost no weight or actually gained 1 or 2 pounds (450 or 900 Gm). Weight reduction was obtained in the 165 remaining patients. The largest reduction of weight in any one patient was 82 pounds (37.2 Kg) in 193 days, or 2.9 pounds (1,315 Gm) weekly. The entire group

lost a total of about 1½ tons in weight. The average total loss per patient was 17.1 pounds (7.8 Kg), which, when calculated for the average duration of treatment, amounted to a loss of 1.4 pounds (635 Gm) weekly. Since this average value included the preliminary periods for each patient, when adequate dosage was not being given, it is seen that a satisfactory rate of weight loss was maintained.

In table 2 the weight losses are segregated according to doses. The same difficulty of correlation arose as with metabolic rates. That is, since only the resistant patients were given the higher doses, increases in loss of weight appeared not to result regularly from increased levels of dosage. This lack of correlation was obviously an artefact due to the procedure used for controlling dosage levels, since it was our constant experience that patients who lost at a given rate on a low dose could be made to lose faster when the dosage was increased.

Questions that often arise are whether more rapid losses of weight are produced in patients not previously treated, and whether those known to be resistant to other therapy can be effectively treated with dinitrophenol. In order to answer these questions the data have been arranged in table 3 according to whether the patients had been previously treated with diet or thyroid, or not at all. It can be seen that those not previously treated received about the same average dose as those who had been previously treated with thyroid or diet, or both. All the groups lost weight at about an equal rate, except those who had previously failed to respond to combined thyroid and dietary control. The latter were more resistant to the dinitrophenol than the others, but still they lost more than a pound weekly during an average of 111 days. This gave an average loss of over 16.2 pounds (7.3 Kg) for each patient, as compared to the 17.1 pounds for the whole series. In other words, each patient lost about the same total weight, but at a slower rate.

SYMPTOMS

It was an almost invariable experience that a therapeutically effective dose of dinitrophenol produced symptoms of increased heat production, which were

TABLE 3—Influence of Previous Type of Treatment on the Rate of Response to Dinitrophenol

Previous Treatment	Number of Cases	Average Daily Dose of Dinitrophenol Gm	Average Duration of Dinitrophenol Days	Average Loss Pounds per Week
No diet or thyroid	99	0.32	82	1.45
Only thyroid	17	0.33	89	1.47
Only diet	26	0.35	91	1.55
Diet and thyroid together	23	0.33	111	1.02

noticed by the patient. These consisted usually of a sensation of warmth with increased perspiration, sometimes sufficient for discomfort. In a few individuals there was some dyspnea on exertion, due presumably to an increased need for oxygen. A few patients had sensations of languor or muscular weakness, but an equal number felt more active and subjectively improved. Two or three, already mentioned, were made so much more hungry that they actually gained weight while under treatment. Others, however, were less hungry than before, so that there was no consistent change in appetite.

⁹ We are indebted to Miss Elizabeth Hines for assistance in these determinations.

The patients were urged to drink liberally of water, since otherwise the large volumes of fluid lost by sweating resulted in too highly concentrated urines. The high water intake also helped to maintain the volume of the perspiration and thus to dissipate the excess heat production without significant increase in body temperature. Distressing symptoms of excessive heat production were most pronounced in patients given larger doses without adequate preliminary building up of tolerance by means of slowly increasing doses. It appears reasonable to assume that physiologic adaptations can be made to the increased heat production just as in case of changes in external temperature. By allowing adequate time for such adaptation, the sensations of heat are minimized and the patient's comfort is increased.

BLOOD CHANGES

Several case reports have appeared recently,¹⁰ indicating that dinitrophenol may cause attacks of agranulocytosis. Animals⁸ have failed to reveal any evidences of alterations in the red or white blood cells even when extratherapeutic doses of dinitrophenol were given for periods of six months. None of these 170 patients developed agranulocytosis or any condition that could be ascribed to a reduction in leukocytic activity.

the blood count was made. If dinitrophenol interfered with leukocyte production, a mechanism of agranulocytosis, there should be some evidence of a progressive shift in the white cell counts as the total dosage increased. In table 5 the patients are divided into four groups according to the total dose of dinitrophenol each one had taken. For the sake of simplicity, the irrelevant counts have been omitted from the table.

It is obvious in table 5 that there is a lack of evidence of a progressive decrease in the white cell count or polymorphonuclear percentage as the total dose of dinitrophenol increased, even though very considerable amounts of the drug had been taken, especially in the last group.

Hence it is concluded from these observations of a rather large series of patients that dinitrophenol did not affect the blood cells, contrary to the assertions of others. At the same time we cannot deny the existence of the changes observed by others under their different conditions. It appears certain that agranulocytosis is not necessarily a constant or even a probable resultant of proper medication with dinitrophenol, at least, it is not due to a direct action of the drug. The occurrence of this rare disease is probably the manifestation of some preexisting idiosyncrasy or defective constitution.

TABLE 4—*Effect of Dinitrophenol on Red and White Blood Cells*

	Red Blood Cells Millions	Hemo- globin per Cent	White Blood Cells Thousands	Polymor- phonuclear Leukocytes per Cent	Small Lympho- cytes per Cent	Large Mono- nuclears per Cent	Transi- tionals, per Cent	Eosino- phils per Cent	Baso- phils, per Cent
Before medication									
Average	5.0	.01	7.3	54	35	5.0	0.0	2.1	0.3
Range	(4.3-5.7)	(.78-.93)	(4.7-10.5)	(43-59)	(23-43)	(2-11)	(0-3)	(0-4)	(0-1)
During medication									
Average	5.1	.85	8.5	58	33	4.3	0.0	1.9	0.5
Range	(3.5-6.1)	(.72-.97)	(4.1-15.0)	(36-90)	(7-61)	(0-11)	(0-3)	(0-5)	(0-3)
After medication									
Average	4.7	.93	7.3	62	31	2.0	0	1.3	0.3
Range	(3.7-5.4)	(.76-1.00)	(5.4-9.8)	(50-72)	(20-33)	(2-4)	(0-0)	(0-2)	(0-1)

Nevertheless, when this possibility was first suggested, blood counts were made on all the available patients under treatment with dinitrophenol, as well as on those who had already completed their therapy. A total of sixty-two cases were thus studied, including eight new patients in whom counts were also made before administration of the drug. The average results, together with maximum and minimum values, are shown in table 4. It can be seen that the values for red cells and hemoglobin have a normal distribution.

This is in agreement with our previous results. The leukocyte count during dinitrophenol administration averaged 8,500 cells per cubic millimeter, and the lowest count was only 4,100, all of which is well within normal limits. Differential counts also gave no indication of a decrease in production of polymorphonuclear leukocytes. Therefore, the influence of the drug on the blood picture as observed in this series may be regarded as entirely negative.

There still remained the possibility that there might be some small progressive change which might be masked by the method of averages used. Therefore the data were rearranged according to the total amount of dinitrophenol taken by each patient up to the time

in the individual patient, in whom dinitrophenol or any other drug or toxin may act merely as a precipitating agent.

BLOOD PRESSURE AND PULSE RATE

Blood pressure and pulse rate changes were carefully observed in seventy-six of these patients. Control readings (before medication) were obtained on three different days, the median of three or more readings obtained on each day being used. The patients were arbitrarily divided into a hypertensive group (those with a systolic blood pressure above 150 mm of mercury) and a normal group. There were thirty patients in the former series and forty-six in the latter. In the normal group the fall of systolic blood pressure averaged 9.4 per cent, with a range of from a 15 per cent increase to a 28 per cent decrease. In the hypertensive group the effect was greater both in absolute values and in percental changes, since the average fall was 12.6 per cent, with a range of from a 3 per cent increase to a 38 per cent decrease. Patients already hypotensive showed little or no further decrease in blood pressure. The fall in diastolic pressures of the normal group averaged 10.6 per cent, with a range of 28 per cent increase to 33 per cent decrease. In the hypertensive group, the average diastolic pressure fell 11.7 per cent, with a range of from 25 per cent increase to 43 per cent decrease. The pulse rate changed in both groups less than 5 per cent and hence was practically unaltered.

From these results it appears that dinitrophenol had little or no direct effect on the systemic blood pressure.

and that such changes as occurred were probably due to loss of body weight. Many obese and hypertensive patients showed no fall in blood pressure, even after large losses of weight. This maintenance of elevated blood pressure, in spite of weight loss, was most frequent among those individuals whose original systolic pressures were 200 mm of mercury or more. While loss of weight is therapeutically indicated in obese patients with hypertension, it cannot be guaranteed that every individual receiving dinitrophenol will obtain a complete result, i. e., both fat and blood pressure reductions.

SIDE ACTIONS

No toxic symptoms occurred in patients taking a daily-dose of less than 300 mg of sodium dinitrophenol. Therefore the group in which reactions occurred was a smaller one, composed of 100 patients who took this dose or more for at least six weeks. Some kind of a side action occurred in twenty-eight patients in this high dosage group. The two most troublesome symptoms were skin rashes and peripheral neuritis. Either of these reactions demands immediate withdrawal of the drug, but neither form a permanent contraindication to dinitrophenol therapy. It was exceptional to find either complication recurring in the same patient.

Skin reactions occurred in twenty-three of these patients. One third of them consisted only of transient itching without a rash. In the remainder there were both pruritus and visible skin lesions, either urticarial or maculopapular in character. The urticarial lesion was about twice as frequent as the maculopapular. After the early days of this study, the patients were warned to discontinue the drug at the first indication of itching or skin rash, since which time none of the lesions have progressed beyond the maculopapular stage, and the incidence of severe skin manifestations has fallen to zero. In a number of instances the skin reaction disappeared spontaneously in spite of the continued administration of the drug. In two patients who continued taking dinitrophenol after the appearance of urticaria, alarming symptoms of systemic poisoning developed. One of these patients had a known allergy toward strawberries, and her skin reaction followed promptly on the eating of a bowl of this fruit at the beginning of the season. It is a question in her case whether the dinitrophenol had any causative role in this skin reaction or perhaps merely aggravated it. The symptoms in both patients seemed referable to increased capillary permeability, with escape of fluid into the tissues. Massive urticarial wheals covered the body and extensive localized edematous collections appeared in various regions. Complete anuria persisted over a period of twenty-four hours, although the first specimen of urine voided showed no albumin, sugar or abnormal microscopic elements. The temperatures were elevated in the allergic case up to 103 F and in the other case to 101 F. The subjective complaints were itching and burning of the skin, great weakness and prostration, and faintness on exertion. The acute discomfort abated after seventy-two hours although neither patient was able to leave bed for a week. Treatment of these severe skin reactions was limited to bed rest, forced fluids and cooling local applications. Hypodermic administration of epinephrine afforded temporary relief from the pruritus and urticaria. Neosynephrin in oral doses of 0.1 Gm every two hours gave no relief. This type of skin reaction has been dis-

cussed previously by us⁷ and in a number of publications by others¹¹ and need not be considered further here.

Exacerbation of a preexisting epidermophytosis was observed in four patients. The rapid spread was doubtless due to the increased sweating, which tended to keep the skin moist and macerated. A similar observation has been reported by Faddersbøll.¹²

Some manifestation of peripheral neuritis occurred in eighteen patients. Most commonly affected were the legs and feet (thirteen patients), but the arms and fingers were involved in ten patients and the tongue in five. Effects on the tongue were manifested by loss of taste, especially for sweet and salt, and numbness and tingling. A similar result has been reported by Hunt.¹³ In the extremities, the symptoms consisted of various paresthesias, such as numbness, "pins-and-needles," and heat and cold. Perception of painful stimuli was increased, but there was a definite delay in the conduction time. In only one case was motor weakness present, as shown by decreased tendon reflexes and partial foot drop. This weakness disappeared entirely one week after dinitrophenol had been discontinued. The sensory changes, as a rule, cleared up more slowly after an average period of three weeks. In one case, symptoms persisted for two months. The changes in peripheral nerves came on so slowly that no difficulties were encountered in diagnosing them,

TABLE 5—Relation of Total Dinitrophenol Dosage to White Blood Cell Counts

Total Amount Taken Gm	White Blood Cells Thou sands	Poly morpho nuclear Leukocytes per Cent	Small Lympho cytes per Cent	Large Mono-nuclears per Cent
Controls before dinitrophenol	7.3	54	38	5.6
0.1 30	7.9	58	34	4.9
0.1 60	8.9	58	37	3.4
0.1 90	8.2	56	30	4.1
0.1 198	8.0	56	37	3.2

or in stopping the drug before significant damage had occurred. After a recovery period, the patients usually resumed treatment of a lower dosage level without further symptoms.

COMMENT

The results obtained by us leave no doubt that dinitrophenol can be administered to almost all obese patients with the object of producing a loss of weight. This is in agreement with previous reports by us and with the experiences of many others.¹⁴ Grant and Schube¹⁵ however, failed to observe a consistent loss of weight in a group of fourteen patients in whom they were studying the effect of dinitrophenol on the blood cholesterol, and Andersen¹⁶ did not find a greater rate of loss of weight in his patients already losing on a 1,000 calorie diet, when they were given dinitrophenol in addition. Other than these two ostensibly negative reports there has been no serious denial of the fact that increasing the basal metabolic rate by dinitrophenol must result in a loss of body weight unless this is compensated for in some way.

Our experience has established the further fact that dinitrophenol will promptly and certainly raise the rate of metabolism in a way and to an extent not approached by any drug previously tried. Therefore, dinitrophenol represents a new and powerful metabolic reagent available for therapeutic experiments and for clinical use. It has, however, the disadvantage of producing in some patients undesirable side actions, which are unpredictable and occasionally alarming. These reactions have occurred mainly in patients receiving large doses of the drug over long periods of time. Attention to the following details should reduce the incidence of undesirable reactions and toxicity to negligible proportions: purity of the drug, slow increase in dosage, maintenance of adequate fluid intake, and prompt discontinuance of the drug on the first hint of an undesirable reaction.

Dinitrophenol should not be used as a routine reducing agent for all cases. Each patient should be handled as an individual problem, those measures being used first which are potentially least harmful. Therefore no patient should be given a drug for the purpose of reducing weight until it is clearly established that dietary measures alone cannot be used successfully, whether by reason of economic or psychic inability to diet properly or because of need for more hurried reduction. In case the patient suffers from hypothyroidism, that fundamental defect should be treated with thyroid as well. Only when these measures fail or cannot be applied should treatment with dinitrophenol be instituted. Treatment with dinitrophenol should therefore constitute the "court of last appeal," where it will be found almost always effective.

CONCLUSIONS

1 One hundred and seventy unselected obese patients were given sodium dinitrophenol (2-4) by mouth for an average of eighty-eight days each, in an average daily dose of 0.34 Gm.

2 The average increase in metabolic rate was about 11 per cent for each 0.1 Gm daily dose.

3 The average loss of body weight was 17.1 pounds for each patient, with an average rate of loss of 1.4 pounds weekly. Patients resistant to dietary or thyroid measures lost weight as well as those previously untreated, but patients who had resisted combined dietary and thyroid therapy lost less rapidly on dinitrophenol than the other groups.

4 The main symptoms of therapeutically effective doses of dinitrophenol were those of extra heat production, namely, sweating, flushed skin, concentrated urine, and sensations of warmth. These symptoms could be controlled to some extent by building up the dosage gradually to the therapeutic level and by ensuring adequate fluid intake.

5 No evidence was obtained in these patients that dinitrophenol affected the blood cells, as shown by blood counts and clinical observations.

6 Side actions, consisting of skin rashes or peripheral nerve changes, were observed in about one fourth of the patients receiving high doses, or in about one seventh of the entire series. These side actions may be largely avoided by stopping medication promptly on the first appearance of any of these changes.

7 Dinitrophenol is a highly effective drug for increasing the metabolic rate and reducing excessive body weight. Medication with this drug is probably indicated in the present state of our knowledge mainly

in those cases in which other potentially less toxic means of treatment cannot be successfully applied. For those obese patients who are resistant or unsuited to other therapy, dinitrophenol is a potent and valuable therapeutic agent.

Sacramento and Webster streets

ABSTRACT OF DISCUSSION

DR. MAURICE BRUGER, New York. Dr. Tainter and his associates have shown that the increased production of heat following the ingestion of dinitrophenol is derived from the combustion of fat rather than carbohydrate. Their studies on the excretion of nitrogen in the urine following the administration of dinitrophenol indicate that protein catabolism is not accelerated. It should be pointed out, however, that determinations of the respiratory quotient after the use of dinitrophenol have not given uniform results: some workers have reported a definite increase in the respiratory quotient, indicating an increased oxidation of carbohydrate, while others have corroborated the results of Dr. Tainter and his co-workers. Drs. Camron V. Bailey, George C. Thosteson and I determined the production of heat in five obese women before and after the administration of dinitrophenol. The respiratory exchange was determined by a modified Tissot method, and the urinary nitrogen content by the Kjeldahl procedure. Our work revealed that (1) the administration of dinitrophenol in doses of 3.5 mg per kilogram increased the total production of heat commensurate with that found by other workers—approximately 40 per cent in from three to four hours, (2) the increased production of heat was derived from the accelerated combustion of both fat and carbohydrate, (3) protein catabolism was definitely spared and (4) appreciable quantities of carbohydrate were burned after the administration of dinitrophenol even though under basal conditions carbohydrate was absent because of previous dietary restrictions. The oxidation of carbohydrate arising from stores partially depleted of this fuel is further evidence of the glycogenolytic action of dinitrophenol. In view of these observations the suggestion is offered that during dinitrophenol therapy an adequate intake of carbohydrate should be allowed, as a safeguard against depleting the store of glycogen in the liver and other tissues and in order to offset some of the toxic manifestations of the drug.

DR. FRANK A. EVANS, Pittsburgh. A study of dinitrophenol in obesity made recently in Pittsburgh confirmed Dr. Tainter's published statements. In other words, dinitrophenol is a drug that increases the basal metabolism and therefore is useful in any clinical condition in which that result is desirable. I question seriously whether obesity is one of those clinical conditions. The oxygen exchange in an obese person is already elevated. Indeed this elevation of metabolism is probably a large factor in the physiologic strain of obesity that makes it such a menace to continued good health. The indication in obesity is not for an increased oxygen exchange but for a diminished intake of energy. Possibly dinitrophenol has a specific effect in fat metabolism. In my opinion this has not been shown. The fact that in the reduction of weight by means of dinitrophenol fat predominantly is burned is not evidence of specificity. Reduction in weight by dietary limitation alone, but in which essential foodstuffs are given in adequate amounts, is at the expense of fat tissue. The caloric deficit to be obtained with safe doses of dinitrophenol is not more than could be obtained by removing from the diet two pats of butter at each meal. If an obese patient will not make such a minor reduction in dietary intake as that, I doubt whether it is worth while to obtain a reduction by any method as after discontinuation of the drug he will probably become as fat as ever. Of the authors' statements the one I can confirm most emphatically is the closing one that the use of dinitrophenol is not the method of choice in the treatment of obesity.

DR. MAURICE L. TAINTER, San Francisco. The amount of fuel burned by dinitrophenol fluctuates since the respiratory quotient can be shown to vary with the degree of muscular

activity Under resting conditions fat is the main source of extra energy, but carbohydrate and protein also may be burned if conditions are changed. Dr Evans is correct in saying that the use of dinitrophenol is not the method of first choice in the treatment of obesity, it is the method of last choice, the method to use when nothing else is effective and when the need for reduction is sufficiently great to justify the admittedly definite risks of the dinitrophenol medication After this paper was prepared for publication, cataracts developed in one of the patients in the series They came on acutely six months after she discontinued the use of the drug It is not possible to decide at present whether such an occurrence is related to the drug, to the restricted or unbalanced diet so commonly used by such patients or to other causes

CORONARY ARTERY THROMBOSIS

WITH TREATMENT BY PROLONGED REST
IN BED AND LOW CALORY DIET,
IMPROVED PROGNOSIS

ARTHUR M MASTER, M.D.
NEW YORK

The prevalence and grave significance¹ of heart disease are being emphasized Nearly 2,000,000 people in this country are suffering from the disease, and deaths from this cause have taken first rank, 224 per hundred thousand of population having been reported for the year 1932 The mortality rate in heart disease is more than twice as high as that in cancer, its nearest rival These figures should not arouse undue apprehension, for it has been pointed² out very clearly that they are the result of "beneficent" causes, namely, the longer life span and the lowered incidence of infectious diseases, tuberculosis, and the like Nevertheless, even the more cheerful writers report that heart muscle disease is markedly on the increase, not only in old age but in the years between 25 and 44 Yet, I shall paint an optimistic picture, in spite of the fact that the most serious of the heart muscle diseases, namely, acute coronary artery occlusion, is my subject

Many clinicians³ have reported the mortality rate from coronary thrombosis as being between 35 and 65 per cent, averaging about 50 per cent These results are based on the attacks studied, no matter whether they happened to be the first, second or third Conner and Holt⁴ gave the first intimation that the death rate following the initial attacks of coronary artery occlusion was much lower than that occurring as a result of later attacks They found the death rate in the first attack to be 16 per cent

This paper contains a summary of an investigation of my private cases The patients were treated either by me alone or in conjunction with the family physician In this series have been included all the deaths that occurred, even though some of the patients died before they could be placed on a low (800) calory diet

CRITERIA FOR DIAGNOSIS OF CORONARY THROMBOSIS

The diagnosis was certain in all the patients who survived Coronary thrombosis, when classic, is an easy diagnosis to make There were severe pain in the chest, particularly substernal, signs of shock, such as grayish pallor, perspiration, feeble pulse, clammy extremities and collapsed veins, a drop in blood pressure, changes in heart sounds, a pericardial rub (if present), a rise in temperature, leukocytosis and, above all, characteristic signs in the electrocardiogram⁴ (That is, characteristic elevations and depressions of RS-T transitions with T wave inversions and Q wave changes)

In a series of eighty-five attacks of coronary thrombosis, occurring in seventy-five patients, the mortality rate was between 9 and 11 per cent The death rate following first attacks was less than 2 per cent These figures are the lowest reported yet The observations and results have been placed in tabular form (table 1)

METHOD OF TREATMENT

Immediate rest in bed was instituted When, occasionally, a patient suffered an attack away from his home, he was very carefully transported there or to a hospital If he was in shock he was kept in bed at the place where he was first seen, if possible

For the first twenty-four, forty-eight or even seventy-two hours of an attack the patient was given very little food, particularly if he was in shock Food was never urged on a patient If nausea and vomiting were present, sips of cold White Rock or Seltzer or Vichy water or bits of cracked ice were offered Usually absolute rest for the stomach is advisable Tea, toast, fermented milks, buttermilk and strained vegetables are added gradually The patient himself will often suggest a food that will relieve his nausea, or at least not aggravate it Sodium bicarbonate alone or in combination with bismuth subnitrate, and minute doses of peppermint were occasionally dispensed for the nausea or vomiting

On the first, second, third or fourth day, depending on the condition of the stomach, the patient was placed on a 750-850 calory diet and remained on it until he was ready to leave his bed It was a well balanced diet⁵ (approximately 80 Gm of carbohydrate, 50 Gm of protein and 30 Gm of fat) containing vitamins and adequate calcium (table 2)

The patient remained on an 800 calory diet for at least four weeks, preferably six, but if he progressed very well or if he was hungry, the quantity of food was slowly increased

The fluid intake was limited to from 1,000 to 1,200 cc, but here again judgment was used On a hot day, if the patient perspired excessively, he was permitted to have more liquids if he so desired As a rule, on a low calory diet patients do not become thirsty, particularly since the food is not spicy Condiments were eschewed Salt was included only in the cooking and was not placed on the food tray

The extreme importance of absolute rest was again and again emphasized to the patient, nurse and family The patient was not permitted to sit up Likewise he

5 This diet is used at the Mount Sinai Hospital in New York and was originated by Miss Adeline Wood head dietitian and Miss Ella Coleman assistant dietitian

was not allowed to feed himself, particularly during the first week or two. His position in bed was carefully changed from time to time to prevent hypostasis in the lungs.

Day and night nurses were retained even if the family finances were strained thereby. Adequate nursing is of indescribable value. The nurses were there to save the patient's energy, to keep away visitors, and to make all

quiet and tranquil. They were enjoined not to do too much—to leave the patient alone, unless they could be of genuine assistance.

Avoidance of infections of the upper respiratory tract is important, as this is a strain on the cardiovascular system, causing a drop in blood pressure and an increase in heart rate. No one who had such an infection was permitted near the patient.

* Treated by method described in paper

† Previous electrocardiograms

I have had no hesitancy in explaining the situation to the patient in a common sense manner. He would be told that he had a wound of the heart and that he must give that organ as little work to do as possible, so that it might heal. It was further explained that physical and mental activity and the partaking and digestion of food entailed added work for the heart by changing blood pressure and pulse rate and stroke output of the heart. Not for a moment, however, was a despondent note struck. In fact, I always assured the patient that he would get well.

The importance of avoiding all irritation and annoyance was made clear. The patient was warned that he was to be the loser in every argument, no matter who was right and no matter how insignificant the point at issue.

The patient was permitted to sit up in from four to six weeks, he was usually in bed for six weeks. Gradually he sat up in a chair, then walked a few steps and made further progress, a little at a time. He was ready to climb steps in from eight to twelve weeks. Patients often required longer periods. Each case was considered on its own data. Rarely, a patient had a return of pain when he first was out of bed, and when this occurred he was promptly put back. On the other hand, many patients felt so well that they insisted on shortening the time in bed.

Only rarely does the sensation of hunger annoy the patient or make him unhappy. Occasionally, particularly in a diabetic patient, the hunger sensation is a problem, but the patient usually becomes adjusted to his diet in a week or two. There are many devices to which one may resort to overcome the pangs of hunger. Clear broth, jellied consommé, tomato juice, and the like have very little caloric value and yet may satisfy the hunger sensation. Furthermore, the patient is advised to eat very slowly and to chew his food well. However, if it appeared that adding 100 or 200 more calories after the first week or two was essential to the patient's comfort, this was done without hesitation.

Digitalis, glyceryl trinitrate, amyl nitrite, epinephrine, and ephedrine⁶ were never prescribed. Morphine and codeine were given liberally. For the severe pain of the attack, in a few instances, morphine was given in doses amounting to from three-fourths to 1 grain (0.05 to 0.06 Gm.) hypodermically, within the first twelve hours, or even within the first two hours. During the initial stage of shock, if the condition of the patient was precarious and if the patient required a cardiovascular stimulant, caffeine was injected subcutaneously or intramuscularly. Heat was applied to the extremities if it made the patient more comfortable. An icebag over the precordium occasionally was welcomed.

No laxatives, cathartics or enemas were ordered for the first three to five days, very rarely did abdominal distention become severe enough to indicate their use any sooner. If a patient required codeine over a period of days, sufficient laxatives were given to keep the bowels open without requiring the patient to strain. It

is well known that patients may die suddenly from excessive straining at stool.

By means of a portable apparatus, electrocardiograms were taken during all attacks but seven. The average number of records was three per patient.

RESULTS

In all, seventy-five patients were treated in the manner described, beginning in 1928, when the first case was so studied at the private pavilion of the New York Hospital. There were sixty-three male and twelve female patients. The average age of patients who survived the attacks was 53 years and of those who died, 63 years. The average age of the male patients was 54, that of the female, 51 years.

These seventy-five patients had, altogether, eighty-five attacks of coronary thrombosis in which the routine procedures just outlined were followed. The mortality was eight deaths in eighty-five attacks, that is, a rate of 9.5 per cent. Considering only first attacks, the mortality was confined to one patient, or less than 2 per cent, whether on the basis of the number of patients or of the total number of attacks (table 1).

In the seventy-five patients studied, eighteen had two occlusions, six had three, and two had four attacks,

TABLE 2—Well Balanced Diet of Low Calory Content

Breakfast	1 small serving fruit without sugar 2 tablespoonfuls of cooked cereal 1 glass of milk buttermilk or skim milk ½ slice of bread or toast coffee or tea without sugar or cream
Dinner	1 cup of broth if desired 2 ounces of lean meat or fish or chicken ½ cup of vegetables 1 small serving of fruit without sugar ½ slice of bread coffee or tea without sugar or cream
Supper	1 ounce of pot cheese or 1 egg ½ cup of vegetables ½ slice of bread 1 glass of milk buttermilk or skim milk

making 108 attacks in all. It is obvious that multiple infarctions are common. The length of time of survival of those who experienced more than one attack ranged from one to fifteen years, and of these twenty-six patients only seven have died.

It is important to know how many patients were able to resume their usual work or routine, following a coronary occlusion. Six of the subjects studied sustained coronary occlusions within the last six months, and it is therefore too early to give the final picture of their physical activity. It is to be recalled that there were eight deaths. Fifty-three patients who suffered attacks were able to resume their usual work or routine. (These people were of the middle and the upper class and hence none had to return to hard labor.) Twelve patients were able to resume light or moderate work. Only six of the seventy-five subjects have remained disabled over periods of from one to seven years, and not one of these is bedridden. That so many were able to resume their routine work shows that the heart, if given a chance, will "come back." These results are their own justification for the mode of treatment employed.

The average stay in bed was forty-three days. The length of time indoors averaged fifty-nine days.

On an 800 calory diet it is inevitable that the patient loses weight.⁷ In many cases this is desirable, particu-

larly if he is overweight. The average loss of weight was 14 pounds (6.4 Kg). Our patients ranged in weight from 103 pounds to 233 pounds (46.7 to 105.7 Kg).

Preceding fifty-nine attacks (69 per cent), hypertension was present, that is, if one considers that a systolic of 150 or more and a diastolic of 90 mm of mercury or more indicates abnormally high blood pressure. Of even more significance is the fact that, of the twenty-six individuals who had more than one attack, at least nineteen had a return of hypertension or showed its presence previous to a subsequent attack. In the treatment, then, following a coronary thrombosis, one object must be to prevent the return of the hypertension either by the administration of drugs or by preventive measures, such as adequate sleep, rest, care of the diet, and loss of weight.

A review of the data (table 1) will disclose that six of the seven who died within twenty-four hours were persons who had had more than one attack of coronary thrombosis. It may therefore be repeated that usually patients do not die in their first attack of coronary thrombosis. Moreover, if the patient survives the first twenty-four hours in any attack, he will probably get over that particular attack.

Emphasis must be placed on the role that hypertension plays. All patients who succumbed within twenty-four hours had previously been subject to this disorder. It is therefore apparent that the prognosis is worse in patients who have hypertension.

Of the twelve women in this series, at least ten (83 per cent) suffered from previous hypertension.^{7a}

Three patients in four attacks (51, 53, 78, 82) had pulmonary edema, two of whom (51 and 53) survived. Congestive failure, in the ordinary sense, with swollen ankles, ascites, congested lungs and huge liver was rarely seen in these patients. This condition may come on gradually subsequent to the attack. During the initial stage of shock signs of slight liver enlargement or adventitious signs at the lung bases, or both, were seen in at least twelve attacks.

Oxygen tents were used on six patients (37, 38, 51, 79, 81, 82), three of whom lived (37, 38, 51). Many of the patients who were gravely ill, however, improved without the aid of oxygen.

There has been much discussion concerning the prognostic importance of the location of the infarct, whether on the posterior or on the anterior aspect of the left ventricle. Characteristic electrocardiographic⁸ Q and T wave changes in lead 1 are indicative of anterior wall injuries and changes in lead 3, of posterior wall injuries of the left ventricle. Twenty-six patients showed the former type and thirty-nine the latter. The prognosis was practically the same in the two locations (table 1).

COMMENT

It is believed that near starvation for the first day or two of an attack is of great value to a patient who has sustained a coronary thrombosis. A similar view is held regarding the subsequent treatment with the 800 calory diet. The physician who comes in contact with an individual who has a coronary artery thrombosis, or even an anginal syndrome, knows that a full meal fre-

quently brings on pain. Heberden⁹ knew this as far back as 1768. Roemheld¹⁰ has thoroughly investigated the "gastrocardiac" syndrome and believes that it is caused by distention of the stomach, by elevation of the left leaf of the diaphragm and also by reflex and toxic products of digestion. Babkin¹¹ recently reviewed the work of the Russian Rosenkov, who stated that after a meal toxic substances are elaborated, causing coronary artery constriction. These substances were not found in the fasting blood of the dog. Wayne and Graybiel¹² emphasize the point made known by Grollman¹³ that the work of the heart is increased after a meal. A heavy meal is too much for a heart in which the coronary circulation is already affected.

That a lowered basal metabolic rate decreases the velocity of the blood flow and diminishes the work of the heart has been demonstrated by Grollman¹⁴ and by Blumgart¹⁵. Jaffe, Dack and I¹⁶ have shown that the basal metabolic rate of a patient placed on an 800 calory diet will fall to —20 and —30 per cent. Hence the further advantages of treatment with a low calory intake.

Blumgart, Levine and Berlin¹⁷ have advocated subtotal thyroidectomy for cases of congestive failure and angina pectoris when they are intractable to the more common forms of treatment. Following the operation, they give their patients small doses of thyroid to maintain a basal metabolic rate between —20 and —30 per cent, such as was obtained by the 800 calory diet. It is therefore possible that this low diet over a period of from three to four months or more may produce results comparable to the more or less permanent effects of subtotal thyroidectomy, obtained by the Boston group.

The low calory diet is not merely a scientific theory, for it has been observed clinically that patients lose their pain more quickly and are less apt to have gastrointestinal complaints. Their vital capacity, blood velocity, venous pressure and blood pressure¹⁸ return more quickly to normal.

Rest in bed lowers the basal metabolic rate, diminishes the work of the heart and gives an opportunity for collateral circulation to form around the infarcted region. I advise keeping the average patient in bed for a minimum of six weeks, but there are many who require months in bed. Each case must be treated according to its signs and symptoms. That sufficient rest in bed is of extreme importance seems beyond dispute.¹⁹

The results submitted here are so much better than those previously reported that an explanation of this difference should be offered. Except for an occasional report, previous investigators have not differentiated between the first and subsequent episodes of coronary artery closure. They too would have found decided differences in the mortality rates of the two types. In addition, diagnostic acumen has undoubtedly been sharpened and the patient is now ordered to bed the moment the diagnosis is suspected. Furthermore, there is evidence that the outlook for a patient with coronary artery thrombosis is somewhat better than published mortality rates would lead one to think. This evidence is in accord with the results of this study. White²⁰ described the case of a man who suffered a coronary thrombosis at 63 and died at the age of 80. In the interim the man performed strenuous feats of physical endurance and died of an apoplectic seizure, with no evidence of heart failure.

SUMMARY

Seventy-five patients in eighty-five attacks of coronary thrombosis were treated by immediate complete rest in bed for six weeks and by a regimen of low calory diet. Eight patients died—only one in a first attack.

Meticulous attention to detail is essential to the management of a patient in an attack of acute coronary thrombosis.

During the initial stage of shock the patient was given very little food.

Low calory diets and small meals prevent dangerous gastro-intestinal-cardiac reflexes or mechanical disturbances, they also lower the basal metabolic rate and diminish the work of the heart. The heart is given an opportunity to heal and to form collateral circulation.

Morphine and codeine were used liberally for severe pain. Glyceryl trinitrate, amyl nitrite, digitalis and epinephrine were considered dangerous.

The prognosis for the first attack of coronary artery thrombosis is considered very good, usually a patient does not die in his first attack.

About 70 per cent of the attacks occurred in hypertensive patients. A hypertension is generally present preceding a subsequent attack.

It is probable that in women a coronary thrombosis takes place only when hypertension is present.

The prognosis is better in cases in which the blood pressure is not high.

The prognosis of patients with infarcts on the anterior or posterior surface of the left ventricle is equally good.

Multiple attacks of coronary thrombosis are common.

A patient who dies within twenty-four hours presumably has had previous attacks of coronary thrombosis and has probably suffered from marked hypertension. If the patient lives through the first twenty-four hours, the chances are he will survive that particular attack.

Congestive failure is usually absent during the first attack of acute coronary thrombosis.

Patients returned to their usual routine life or work following at least 62.5 per cent of the attacks and resumed light to moderate activity in at least 14 per cent.

PASSIVE IMMUNITY IN INFANTS AND THEIR RESPONSE TO DIPHTHERIA TOXOID

PRELIMINARY REPORT

JOSEPH GREENGARD, M.D.
AND
HAROLD BERNSTEIN, M.D.
CHICAGO

The most favorable age at which vaccination against diphtheria should be carried out is a matter of considerable disagreement. It is desirable to obtain immunity at as early an age as possible. In private practice, pediatricians have been recommending such active immunization at the end of the first year. Recently, vigorous public health programs have been advancing the age to 6 months. There are two factors that enter into the question of the advisability of vaccination at this age: (1) the fact that young individuals are poor formers of antitoxin and (2) the fact that a considerable proportion of infants still retain their passive immunity at this age. In a recent publication, one of us¹ has shown that infants under 6 months of age respond to vaccination less favorably than those over this age, in that the percentage immunized is smaller, and, even when immunity is obtained, it is less likely to endure than in the older group. After 6 months, however, the proportion immunized is high, around 95 per cent, and the immunity is persistent. From the standpoint of the age of the individual, therefore, 6 months may be selected as a favorable period for antidiphtheria vaccination.

In both private work and public health programs, however, it is impracticable to do preliminary Schick tests before vaccination with toxoid is carried out. At 6 months of age about half of all babies still retain their passive immunity. In the group at St. Vincent's Hospital, where this problem has been under investigation, 68 per cent of the babies still show a negative Schick test at 6 months, while at from 9 months to 1 year 70 per cent are positive.² This is in agreement with the mass of statistics that has been gathered.

Our purpose in this investigation was to determine whether or not passive immunity, as evidenced by a negative Schick test, would interfere with the active production of antitoxin. Preliminary Schick tests were done on all infants and vaccination was carried out in the usual manner employed at this institution.³ This consists in the administration of two 1 cc doses of diphtheria toxoid at a one week interval and is the technic followed in the public health program of the Chicago Board of Health. Both negative and positive reactors were vaccinated and follow-up Schick tests then done one month, three months, six months, nine months, one year and eighteen months after the second injection, when possible. In this manner the results of vaccination could be followed in both the infants who had lost their passive immunity (positive reactors) and in those who still retained it (negative reactors).

The results are given in table 1. There are seventy-four cases in this series, forty-four of which were

Schick positive before vaccination and thirty Schick negative. In the Schick positive group thirty-nine, or 88 per cent, became negative after vaccination and remained so, while in the Schick negative group twenty, or 66⅔ per cent, turned positive at varying times after the second dose of toxoid. This last figure, it will be noted, is very similar to that obtained in infants who have not been vaccinated, i. e., about 70 per cent Schick positive at from 9 to 12 months. Since the age of the infant is also a factor in the production of immunity, the control group (Schick positives) must be compared with the test cases from this standpoint also (table 2). It will be noted that there are naturally more older infants in the Schick positive group, so that the two are not precisely parallel, though the infants under 6 months are almost identical in distribution. The difference in immunity response is so striking, however, that the factor of age alone cannot be held accountable. This study is continuing with a view to accumulating a larger series over 6 months of age.

COMMENT

Park⁴ has stated that immunization with toxin-antitoxin mixtures was inadvisable in the presence of passive immunity and ascribed the failure of the production of antitoxin in such individuals to overneutralization of the mixture. So far as we know there are no clinical reports relating to the effect of passive immunity on vaccination with toxoid. Several reports of animal experiments are significant in this connection. Moloney and Fraser⁵ have shown that under certain conditions passive immunity will retard or prevent the establishment of active immunity produced by diphtheria anatoxin in the guinea-pig. They have also shown that there is a difference in the effect of homologous and heterologous serums in this respect, the latter being excreted much more rapidly than the former.

4 Park W. H. cited by Blum Julius. Age Factor in the Active Immunization of Infants Against Diphtheria. J. A. M. A. 98:1627 (May 7) 1932.
5 Moloney P. J. and Fraser C. J. Effet de l'immunité passive sur l'immunisation active par l'anatoxine diphtérique. Ann. Inst. Pasteur 43:129 (Jan.) 1929.

Surraco⁶ has shown that injection of heterologous anti diphtheria serum rendered vaccination with diphtheria anatoxin ineffective in the guinea-pig. Ramon and Lafaille⁷ similarly have shown that mixture of tetanus anatoxin and antitoxin failed to immunize guinea pigs and rabbits and their injection also interferes with subsequent attempts at specific immunization. These experiments confirm the results in our babies. Here we are dealing with passive immunity with a homologous

TABLE 2—Age Distribution Before Vaccination

	Schick Negative	Schick Positive

From 3-6 months*	17	18
From 6-9 months*	3	10
From 9-12 months*	1	3
Over 1 year	2	5

serum, which consequently is long lasting. When vaccination is carried out at 6 months of age in the ordinary routine manner, without preliminary Schick testing, about half of the infants inoculated will still retain their passive immunity. According to our results, few if any of these will be immunized. Such a situation is of great importance, since it invalidates an immunization program to a great extent. If immunization is to be carried out at 6 months, preliminary Schick tests should be done and only the positive reactors inoculated; the negative reactors being retested and vaccinated as positives appear. If this cannot be done, routine immunization might well be withheld until from 9 to 12 months, when practically all babies will have lost their passive immunity.

SUMMARY AND CONCLUSION

Preliminary Schick tests were done on all infants and vaccination with diphtheria toxoid was carried out in both the positive and the negative reactors. The negative reactors, i. e., those who still retained their passive immunity, demonstrated a positive Schick test in two thirds of the cases, the course of their passive immunity corresponding closely to that of infants who have not been vaccinated. The positive reactors, control series, turned negative and remained so in 88 per cent of the cases. We may therefore conclude that passive immunity in infants interferes with the development of antitoxin in response to vaccination with diphtheria toxoid. Such vaccination, therefore, should not be done in young age groups without preliminary Schick testing.

The Girl Approaching Puberty—The cardinal facts to impress on the girls are these: (1) the importance of building up and caring for her body during this formative period of her life, (2) the normality of menstruation and the fact that in itself it should not cause any interference with the girl's life activities. If, in addition, the girl is fortunate in having some one explain to her in simple fashion the significance of such body phenomena as menstruation, or enlighten her as to a few simple facts as to the reproductive phenomena in general, it is all the better for the girl. No one can quite take the place of the mother in instructing her daughter in the simple and beautiful truths of the reproductive life and its various manifestations.—Novak Emil. The Woman Asks the Doctor, Baltimore: Williams and Wilkins Company, 1935.

ROENTGEN DIAGNOSIS OF TUMORS
OF THE BREAST

MAX RITVO, MD
P F BUTLER, MD
AND
E EVERETT O'NEIL, MD
BOSTON

Roentgen examination affords a reliable and comparatively easy method of studying the structure, physiology and pathology of the female breast. Neoplasms and other pathologic processes in the mammary glands can be visualized on the roentgenogram, also the changes incidental to menstruation, pregnancy and the menopause. By clinical examination it is often impossible to determine whether or not a mass is present in the breast. Transillumination has thus far not proved dependable as a means of diagnosis. Formerly it was necessary to resort to biopsy or operative removal in cases of suspected or questionable new growth of the mammary gland in order to make a definite diagnosis. The necessity of repeated palpation and diagnostic operation is greatly lessened by roentgen studies.

We have made roentgen examinations of the breast in 320 cases during the past three years and are of the opinion that it is possible to determine the presence of a pathologic process with a high degree of accuracy by this method. Many clinicians do not appreciate the value of the x-rays in studying the mammary glands, and the majority of roentgenologists are not carrying out this examination at present. Any means of increasing the accuracy of diagnosis or facilitating early diagnosis is of value. We are therefore presenting the technical and diagnostic aspects of the subject in considerable detail with the hope that others will be stimulated to carry out similar studies.

HISTORICAL NOTES

Warren¹ in 1930 reported a series of 100 cases of lesions of the breast studied roentgenologically and demonstrated the value of this method for the first time. Seabold² discussed the roentgen diagnosis of diseases of the breast² and also the technic of the examination³. Fray and Warren⁴ in 1931 considered the differential points in the study of carcinoma and mastitis. Lockwood⁵ in 1932 and subsequently⁶ in collaboration with others called attention to the importance of the x-rays in the diagnosis of breast tumors and correlated the symptomatology with the roentgen observations. Vogel⁷ discussed the diagnostic and prognostic significance of the x-rays in the study of mammary gland tumors. Remann and Seabold⁸ compared the roentgen obser-

vations with the pathology. Ries⁹ showed that it is unsafe to inject foreign material such as iodized poppy-seed oil 40 per cent, into the milk ducts for diagnostic purposes because of the danger of resultant infection. Several other contributions emphasizing the value of the x-rays in the examination of the breast have appeared in the European literature¹⁰.

ANATOMY

The adult female breast is composed of a number of lobes subdivided into lobules and separated from one another by connective tissue and elastic septums. Histologically the breast is made up of three prime elements: (1) glandular structures, (2) fibrous tissue and (3) fat. The glandular lobules are composed of rounded alveoli. The lactiferous ducts number from fifteen to twenty, converge centrally toward the alveoli and unite to form the canals that conduct the milk to the nipple. The ducts and acini are lined with epithelium which rests on a layer of smooth muscle and is continuous with the epithelium of the body. During pregnancy the gland tissue undergoes hyperplasia and the ducts elongate. At the same time the connective-

Fig. 1.—Normal breast (multipara, aged 40). The ducts are seen as linear striations in the lower and middle portions of the breast shadow. The acini are indicated by the arrows in the proximal and the middle portion of the breast. The nipple stands out clearly as a rounded area of density.

tissue diminishes markedly, so that the lactating breast is made up almost entirely of ducts, acini and blood vessels, with little or no fibrous elements. After the cessation of lactation the acini atrophy but the ducts do not and as the breast shrinks there is marked convolution and apparent increase in the number of ducts. During each menstrual period similar but less marked changes occur. The fibrous tissue forms septums between the lobes and lies outside the smooth muscle on which the glandular epithelium rests. As previously stated, the breast during pregnancy is made up almost entirely of glandular tissue, after lactation there is a marked hyperplasia of the fibrous elements. The fat lies in the lobes in a loosely constructed fibrous tissue containing elastica. The amount of fatty tissue varies with the size and conformation of the breast.

X-RAY TECHNIC

The x-ray studies require no previous preparation of the patient and cause no pain or discomfort. No special apparatus is required and the examination may be carried out by any competent radiologist. Because of the necessity of obtaining sharp films with the

TUMORS OF BREAST

The patient bares the chest and breasts, lies face up on the x-ray table and is turned slowly to the side until she is in such a position that the central x-ray beam may pass through the breast to the film without striking the ribs. The upper arm of the side being examined is placed at right angles to the body with the forearm alongside the head, palm upward.

AL

However, the breast must always be as near under it as possible. The central beam is focused over the film as possible. The central beam is focused over the middle of the breast and slightly outside the lateral chest wall. The film should include the entire axilla, the ribs for a distance of several centimeters and a portion of the adjacent lung. The examination is best carried out at the middle of the intermenstrual period. Serial examinations are of great value.

THE ROENTGEN PICTURE OF THE NORMAL BREAST

ROENTGEN PICTURE OF THE NORMAL BREAST

The mammary gland lends itself readily to roentgenography by virtue of its anatomic position. With the exposures commonly used for the study of the bones or internal organs however, the entire breast casts a shadow of almost uniform density. By means of the soft tissue technic, previously described, it is possible to bring out the slight differences in the densities cast by the glandular structures fibrous elements and the fatty tissues, which comprise the normal breast and to obtain x-ray films of diagnostic value. The changes incidental to menstruation pregnancy and the menopause cause alterations in the breast tissues which though very slight, are demonstrable on the roentgenogram. Pathologic processes are visualized because they cause distortion of the structures or are either more or less dense than the normal tissues of the

The Bucks diaphragm is used and the films are made stereoscopically. Speed is essential in making the roentgenogram to eliminate motion due to movement breathing or transmission of the cardiac impulse. A soft tissue technique is used as follows: double intensifying screens, from 30 to 60 peak kilovolts in exposure of from one half to two seconds. 30 milli-

amperes, 30-inch target film distance. Roentgenograms of both breasts are always made for purposes of comparison. It may be necessary to make films of the affected breast at different angles and with varying exposures to bring the suspected area into view. If the breast is large and pendulous, it may be helpful to place a support, such as a small inflated rubber bladder,

mammary gland The film of a normal patient is reproduced in figure 1. The breast appears as a rounded or roughly triangular shadow with the ribs and upper arm faintly shown. The ducts are seen as multiple sharply defined irregular linear striations varying in width from 1 to several millimeters. These striae are somewhat feathery and traverse the breast shadow obliquely to converge toward the surface in the region of the nipple. The axilla lie near the chest wall in the middle and lower portions of the breast shadow. They consist of numerous fine irregular, mottled areas of a density continuous with the shadows of the ducts. The axilla and ducts are usually arranged in a roughly triangular form with the base of the triangle near the chest wall and the apex directed toward the anterior and inferior portion of the mammary gland. The main mass of the breast appears as a homogeneous or slightly mottled area of density, varying with the amount of fatty tissue. Mammary glands with large amounts of fat, while difficult to examine properly by palpation, lend themselves readily to roentgen study and produce sharp roentgenograms with good contrast. The flat, poorly developed breast may produce a more homogeneous shadow on the roentgenogram and is therefore more difficult to roentgenograph satisfactorily. Lesions

in the outer and middle portions of the breast are usually visualized with ease. Small masses in the inner and upper portion of the breast may be seen only with difficulty.

The skin and subcutaneous structures are shown in profile along the outer edge of the breast and are less dense than the main mass of the mammary gland. The nipple may be visualized as a rounded or oval area of

Fig 5—Cystoplasia (cystic mastitis) with cysts. The typical changes of cystoplasia (see text) are well shown. Multiple cysts are present; the arrows in the upper portion of the right breast indicating a characteristic cyst. In the lower pole of the breast (F) there is an area of fibrosis the result of a breast abscess that was operated on ten years ago.

density, especially if pigmented (fig 1). Extending along the base of the breast is a thin, linear area of radiance and beneath this appear the pectoral muscle, ribs and lung. The normal axillary lymphatic structures are not demonstrable. Enlarged lymph nodes may cast a shadow. Calcified glands are seen clearly. The axillary hair may be seen as thin, thready shadows.

The breast is not a static organ but is constantly undergoing changes that are associated with menstruation, pregnancy, involution and so on. These physiologic alterations cause constant variations in the roentgen picture of the breast. Beginning about a week or ten days before the onset of the menses, the linear striae become denser and thicker and the entire breast increases in density. When the menstrual flow has begun, the striations become less dense, during the subsequent ten days the breast slowly returns to its previous condition and the normal resting stage reestablishes itself. It is therefore advisable to inquire into the menstrual history, the roentgen examination is best made at about the middle of the intermenstrual period.

In the later months of pregnancy, the breast becomes increasingly dense and the linear striations diminish progressively and finally completely disappear. During lactation the breast is markedly enlarged and presents a uniformly dense shadow. After the menopause the breast may decrease in size. The linear markings show a diminution in number and size but lie more closely together and are usually slightly increased in density.

PATHOLOGIC CONDITIONS OF THE BREAST

Mazoplasia (chronic mastitis)—Formerly breasts were classified as normal or as showing chronic or cystic mastitis. In the light of recent studies this classification has been found to be unsatisfactory. The state commonly known as chronic mastitis is in reality

a physiologic process and not in any sense inflammatory. For this condition Cheatle and Cutler¹¹ have suggested the name mazoplasia. The cases previously grouped as chronic cystic mastitis are by these authors now classified as "cystiphorous desquamative epithelial hyperplasia." We feel that the classification of Cheatle and Cutler is much more nearly in accord with the physiology and pathology of the breast than the previous terminology and strongly urge its universal adoption.

In cases of mazoplasia there is desquamation of the epithelial cells in the ducts and acini, formation of new ducts and acini, and hyperplasia of the fibrous tissue. The cells that have been shed die and accumulate in the ducts and acini causing distention, pain and a nodular irregular feeling when the breast is palpated. These changes may occur in patients of any age but are most frequent in those between 30 and 40, especially in multiparas. Mazoplasia appears to be associated with a disturbance of the hormones, as these patients frequently have a history of short, scanty menses. Cysts are not seen in this type of breast, nor do papillomas or malignant growths develop in these patients. Fibroadenomas do occur, however, and appear to be the only pathologic process that can be traced to mazoplasia. Mazoplasia is not a surgical condition and usually disappears at the menopause, bearing out the opinion of Cheatle and Cutler that it is a physiologic rather than a truly pathologic process.

The roentgen picture of mazoplasia is characteristic. The breasts cast a diffuse hazy shadow with areas of slightly mottled and increased radiance distributed at irregular intervals. The linear striations of the ducts and acini normally present are entirely absent or nearly so over the main mass of the breast shadow. A few of the linear markings may be visible in the region just below the nipple. There is usually a narrow band of increased radiability along the outer margin of the breast due to fatty tissue deposited in this region. There is no retraction of the nipple and the skin of the mammary gland is smooth and regular in outline. No glands are present in the axillae.

Cystoplasia (cystic mastitis, cystiphorous desquamative epithelial hyperplasia)—The condition formerly classified as chronic cystic mastitis is according to the terminology of Cheatle and Cutler, now termed cystiphorous desquamative epithelial hyperplasia. As a short name for this we suggest the term "cystoplasia"

and shall use this term in order to avoid repeating the long and cumbersome name suggested by Cheatle and Cutler. Cystoplasia begins with a desquamation of the epithelial cells of the ducts and acini as in mazoplasia. However the condition goes on to the formation of

Fig 6—Breast abscess (patient aged 32). Her child had been nursing for fourteen months. Five days before the left breast became hot, tender and markedly swollen. Operation revealed an extensive abscess of the left breast. Incision and drainage resulted in a cure. Glands in the axilla are indicated by arrows.

¹¹ Cheatle, C. L. and Cutler, Max. Tumors of the Breast. Philadelphia: J. B. Lippincott Company, 1931.

cysts and thus differs from the physiologic processes of mastoplasia. Cystoplasia is not inflammatory in nature, hence cystic mastitis is not a proper term.

This condition usually begins at about the age of 30. In many patients the process appears to cease in the stage of cyst formation and the end result is the formation of multiple cysts of varying size scattered throughout the breast. In some instances the changes are progressive and benign lesions such as papillomas, form. After about 50 carcinoma may develop in this type of breast. It is as yet uncertain what percentage of cases undergo malignant degeneration but it is known that cystoplasia is potentially dangerous.

The roentgen picture of cystoplasia is a very typical one. The linear striations formed by the ducts and acini show increased width and density. These striae are more irregular in outline and are separated from one another by a wider space so that they may appear distributed over practically the entire breast shadow. The striations converge at the apex of the gland and form a broad band extending to the nipple. Scattered irregularly throughout the entire shadow of the mammary gland are multiple trabeculated areas of radiance varying in width from a few millimeters to several centimeters. These areas are sharply defined, have thin linear borders, are more radiant than the normal breast shadow and represent the cystic formations. The entire breast appears denser and thicker than usual. Contraction and scarring occur frequently and result in distortion of the breast structures on the roentgenogram. The area of radiance at the posterior aspect of the breast is preserved. These changes are usually bilateral and are similar in character on the two sides.

Large cysts result from the obstruction of a duct or acinus with consequent dilatation proximal to the point of obstruction. Cysts may be single or multiple and appear as smooth sharply defined oval or rounded shadows in the region of acini and ducts. If they do not contain fluid they are more radiant than the

Fig 7—Hematoma (unmarried woman aged 37). Severe trauma to left breast three weeks before. Painless swelling since that time. The mass was hard, movable, nontender and not adherent to the skin. Arrows indicate the hematoma which was most dense in its central portion and had irregular borders.

remainder of the breast, if filled with fluid their density is greater. The linear striae may be compressed, but they are not invaded or destroyed by the presence of cysts.

Benign Tumors (fibro-adenomas, adenomas, and fibromas).—These tumors occur in breasts which show mastoplasia or are otherwise normal. The neoplasm occurs as a rounded or oval area of density with smooth or slightly irregular borders. The linear markings are

absent or diminished over the region of the mass, else where they are compressed and appear crowded together. The lesion is usually single. Masses in the middle and outer portions of the breast are visualized easily, those in the inner and upper portions, especially if the breast is small, may be demonstrated with difficulty, if at all. Calcification may rarely be present within the mass.

Breast Abscess.—This condition usually occurs in the lactating breast. There is diffuse thickening with irregular density at the site of the lesion. The margins of the abscess are not sharply defined as in the case of a neoplasm but fade off gradually into the breast structures. If a very large abscess is present the breast may be markedly enlarged with a diffuse irregular mottled shadow over its entire extent.

Fig 8—Carcinoma (patient aged 58). A lump in the right breast had been noted for four months. The tumor was dense, sharply outlined and slightly irregular in outline. There was invasion and compression of the linear striae over the lower pole of the right breast. Both breasts showed cystoplasia.

The clinical picture of pain, tenderness, heat and swelling of the breast is well known and usually makes the diagnosis clear. The roentgenogram is of value in demonstrating the size and extent of the lesion and may also be important in the study of the progress of the case. The scars of an old healed abscess may cause irregularities and thickening of the breast structures and may be confused with the earliest stage of a neoplasm. However, serial roentgenograms taken at intervals of a few weeks show no change in the size or character of this type of lesion, and a careful review of the past history elicits the story of an old abscess.

Hematoma and Fibrosis.—A very important, although not a common type of lesion, is the hematoma that forms subsequent to an injury to the breast. This occurs most frequently as the result of an automobile accident in which the driver of the car is thrown against the steering wheel although it may follow any severe trauma. The history is important in arriving at a definite diagnosis, as the clinical and roentgen pictures may closely simulate those of other lesions. On the roentgenogram an area of density is demonstrable in the breast. This shadow varies in size according to the extent of the lesion, is very irregular in outline and is most dense in its central portion with less density toward the periphery. The breast markings in the affected area are obscured or distorted. If the lesion is near the surface, there may be bulging of the outer aspect of the breast shadow. Serial roentgen studies at intervals of a few weeks show the area of density becoming progressively denser and diminishing in size. If there is an increase of the size of the shadow and more irregularity of outline with the passage of time an early malignant condition must be considered. After an interval of several months the mass may become fibrosed, leaving a scar of variable size in the breast. Calcification of the mass may occur with formation of shadows of the density of bone within the area.

Carcinoma of the Breast.—Carcinoma of the breast may be diagnosed with a high degree of accuracy by

roentgen examination We do not feel that the earliest stages of malignancy or early malignant changes in a formerly benign tumor of the breast are demonstrable on the x-ray film However, the method will frequently demonstrate the existence of a neoplasm before it can be diagnosed by other clinical means In moderately or far advanced stages, roentgen examination shows the character and extent of the lesion and may be of great aid in demonstrating axillary gland or rib involvement

The malignant growth is seen as a dense, sharply defined shadow on the roentgenogram The margins of the mass are usually irregular and infiltrating but may in some instances be quite smooth If small the tumor causes little if any distortion of breast structures As the tumor enlarges, the structures are invaded or compressed The neoplasm may be multiple, with two or more areas of varying size in the breast Inversion of the nipple or dimpling of the surface of the breast if present, is demonstrable on the x-ray film Irregular feathery extension into the surrounding breast tissue from the mass of the tumor is very typical of carcinoma Lesions near the nipple often show a dense band extending from the neoplasm toward the nipple the so called bridge of tumor tissue In the presence of cystoplasia a carcinoma appears as a dense shadow of much greater density than the remainder of the breast tissue In cases of extensive, advanced malignancy, multiple rounded irregular masses may replace the greater portion of the breast structure or even occupy the entire mass of the breast

The tumor may extend posteriorly and invade the clear radiant area normally present between the breast and the chest wall Extensions to the ribs or metastases to the ribs of the same or the opposite side are demonstrable roentgenologically and are of great importance in diagnosis and prognosis and in deciding on the course of treatment The study of the remaining breast in patients who have had a breast removed for carcinoma

Fig 9—Carcinoma (patient aged 61) The greater portion of the left breast was involved by the malignant growth A large gland in the left axilla is indicated by the upper arrow Operative confirmation The right breast showed involutional changes

is important Serial roentgenograms of neoplasms of the breast are of great value in determining the rate of growth and the effect of radiation treatment

Glands in the axilla are frequently demonstrable and the breast films should always include the axilla The glands are seen as oval or rounded areas of density varying from several millimeters to 3 or 4 cm in diameter They are smooth and sharply defined and

may be more dense at the periphery than in the central portion Inflammatory glands are usually denser and more sharply circumscribed than malignant glands

SUMMARY

Roentgen examination affords an easy and reliable method of studying the female breast Neoplasms of the breast and other pathologic processes may be visual-

Fig 10—Carcinoma with metastases to the axillary glands (patient, aged 56) A mass in the right breast with palpable glands in the axilla The lower arrows indicate the malignant growth There is absence of the linear striae in this region with compression of the striations in the middle and lower portions of the breast The axillary glands are indicated by the upper arrows Operation revealed scirrhous carcinoma of the breast with axillary metastases

ized The changes incidental to menstruation, pregnancy and the menopause are also demonstrable

The roentgen examination requires no special preparation of the patient and causes no pain or discomfort

Cheattle and Cutler's classification of mastoplasia and cystiphorous desquamative epithelial hyperplasia is used to replace "chronic mastitis" and "cystic mastitis," these terms being unsatisfactory in the light of recent studies We suggest the name cystoplasia to denote the condition of cystiphorous desquamative epithelial hyperplasia

We do not believe at present that the early stages of malignancy or beginning malignant degeneration in formerly benign tumors are demonstrable on the roentgenogram

Tumor masses can be outlined and the character and extent of the lesion determined The existence of a neoplasm may be shown by roentgen examination before it can be definitely diagnosed by clinical means

Glands in the axilla and extension of malignant growth to the ribs are demonstrable on the roentgenogram

Roentgen studies greatly lessen the need of diagnostic operation and repeated palpation of the breast and give information of value in the diagnosis, prognosis and treatment of lesions of the breast

485 Commonwealth Avenue.

ABSTRACT OF DISCUSSION

DR. L. A. POMEROY, Cleveland I wish to discuss this paper not as a roentgenologist but as an observer of a series of patients with tumor of the breast Of thirty-five patients a few were operated on by me, but most of them were patients of my colleagues and were observed through their courtesy In every instance, in addition to the regular physical examination transillumination and roentgen examination of the breasts were performed and the results checked by microscopic examination of tissue removed at operation Neither transillumination nor roentgen examination provides a definite method of distinguish-

ing benign from malignant tumors, but each method may add additional diagnostic data, sometimes obtainable in no other manner. The greatest usefulness of transillumination is in distinguishing an area of hemorrhage (either into a tumor or into breast tissue) in which the shadow is absolutely black. A cyst containing clear fluid usually does not cast a shadow, but the light may be transmitted through it very brightly. In performing transillumination the Cameron and Cutler lights are excellent, but care should be taken that the eyes are always accustomed to the darkness. Roentgen examination does not make it possible to distinguish benign from malignant tumors, but it may show the presence or absence of encapsulation of the tumor, which is an important factor in making a diagnosis.

DR JOHN J. GIBBIE, Philadelphia. This subject represents a marked advance in the diagnosis and treatment of disease of the breast. Roentgen examination of the breast by a skilled roentgenologist is of undoubted value in some cases in helping to establish a definite diagnosis. Patients with disease of the breast are visiting their physicians earlier than they did formerly because they have been educated to do so. Now that they are taking that advice, the physician must be able to make an earlier diagnosis. The advanced case is diagnosed readily enough. It is in the doubtful case that one needs all available information. If a young woman complains of pain in the breast and it is not possible to make a clinical diagnosis, the roentgenologist may be able to show shadows on the roentgenogram that suggest the presence of cystic mastitis or other benign disease. This information may enable the physician to assure the patient that the disease is not serious. Patients should be informed to that effect and relieved of their anxiety. Roentgen examination may enable the physician to make a diagnosis of the presence of malignant disease in some cases; in other cases it may suggest that the disease is benign and in still others it may establish the fact that there is no demonstrable disease of the breast.

PROGRESSIVE ATLANTO-AXIAL DISLOCATION

EDGAR A. KAHN, MD

AND

LUIS YGLESIAS, MD

ANN ARBOR, MICH.

Forward displacement of the atlas on the axis is a comparatively rare condition, ordinarily treated by conservative methods. Operative intervention has been recorded in but few cases and only when pressure myelitis has developed. The more common unilateral or rotary dislocation will not be considered here, since it is a less serious lesion, with a far better prognosis and ordinarily responds to the manipulative method of Walton.¹

The condition we are considering is frequently immediately fatal. In cases in which death does not occur the diagnosis at first may be easily overlooked, since there is usually no evidence of spinal cord injury. The dislocation is ordinarily a progressive one; the seriousness of which is attested only by increasing pressure myelitis or sudden death.

At the time of the original trauma, the common lesion is a fracture of the odontoid process at its base and loosening of the atlanto-axial ligaments with the exception of the strong transverse ligament. The forward displacement at first may be so slight that it is not recognized by x-rays, and the fractured odontoid process may not be apparent without a special technic. It is just at this time that immobilization is so essential to prevent subsequent disaster. After the condition has advanced and is easily recognized, conservative

treatment by traction or immobilization may be tried, but in cases in which forward slipping progresses or recurs, operative surgery must be considered whether pressure myelitis has developed or not. Badgley² of this clinic has stressed this point.

The first operative attempt to reduce an atlanto-axial dislocation that we have found recorded was by Lewis Stephen Pilcher in 1900.³

A man, aged 33, was injured by striking on his head after falling from a ladder. He was able to stand but suffered pain referred to the back of the head and upper part of the neck. The patient had been up and around the house for more than two months when a marked weakness rapidly developed in the right arm and leg. The paralysis increased and the sphincters became involved. In view of the possibility that the cord symptoms might in part be due to pressure from a depressed fragment of a lamina it was decided to expose the axis and atlas. A midline incision was made from the external occipital protuberance to the seventh cervical spine. "No fracture of any lamina was uncovered but a forward dislocation of the atlas on the axis was demonstrated to be present. Careful efforts to correct the displacement were futile. Seven months after operation the patient was still hemiplegic, though normal bladder function had returned. He was examined nine years later. Roentgenograms revealed marked forward displacement of the atlas on the axis. There was a dense mass of callus surrounding and obscuring the outline of the atlas and filling the space between the axis and the base of the skull. The patient was able to walk normally for fairly long distances without much fatigue. Abnormal neurologic changes were present, however, in the upper extremities, the right hand presenting to a moderate degree the condition of 'main en griffe'."

Fig. 1 (case 1).—Appearance on admission July 15, 1933, three days after injury. The depressed skull fracture is seen in the parietal region. The atlas is tilted slightly forward and there is a fracture of the odontoid process.

The progression of the lesion is well shown in this case and it is surprising that it did not terminate fatally. The operative procedure undoubtedly resulted in the ultimate occipitocervical bony fusion, but whether this prevented further progression is questionable. Had the arch of the atlas been removed at the time of operation, there is no doubt that the neurologic signs would have cleared faster and probably have entirely disappeared.

Mixter and Osgood⁴ in 1912 reported two cases of considerable interest.

A boy aged 15 years, had fallen from a tree five weeks previously. Immediate pain and stiffness of the neck had followed. Roentgenograms revealed no lesion that could be accurately interpreted, but a rotary dislocation of the 'atlas or possibly axis' was suspected. Under anesthesia gentle manipulation was carried out, with apparent return to normal. Six months later the patient was again seen because of severe occipital neuralgia. Again roentgenograms failed to reveal the real lesion and a

⁴ Mixter, S. J. and Osgood, R. B. Traumatic Lesions of the Atlas and Axis. *Ann. Surg.* 51: 193-207 (Feb.) 1910.

second manipulation was carried out. The symptoms were relieved for a month following application of a complete plaster helmet, but following its removal they again recurred. Roentgen studies through the mouth and laterally showed a fracture of the odontoid process with forward slipping of the atlas. At operation, the forward displaced atlas was exposed with the spinous process of the axis. "While forward pressure on the anterior arch was exerted through the pharynx" traction was exerted by a silk band passed around the posterior arch of the atlas. "There was firm resistance to replacement and only a slight amount of reposition was accomplished. This was maintained, however, and the atlas firmly anchored by tying the silk band around the hooked spinous process of the axis." The patient was symptom free two years later.

The second patient had been injured five months before in a railroad accident. Roentgenograms showed forward displacement of the atlas on the axis. No cord symptoms were present. Following manipulation, the patient was well for several months at which time symptoms of spinal cord pressure came on gradually and developed into a tetraplegia. At operation the third and fourth cervical laminae were removed. Arches of the atlas and axis were found depressed pressing into the cord apparently from callus formation. These pressing protuberances were removed. Improvement in pressure symptoms continued for four weeks at which time the patient on sneezing, suddenly became paralyzed and died.

Again the progressive nature of the lesion is seen. It is difficult from the description of the second case to determine whether or not the arch of the atlas and lamina of the axis were completely removed.

Elliott and Sachs⁵ report a case in which a man lived for thirty years with an atlanto-axial dislocation. During this time intermittent attacks of paralysis occurred, usually from minor trauma. He was able to be about between attacks. The last attack was fatal. These authors state "If any operation is to be considered in cases similar to the one under consideration, we suggest a laminectomy—removal of a portion of the posterior arch of the atlas."

Fig. 2 (case 1)—Condition August 19. No support was worn during this interval.

A case is cited by Craig⁶ of a youth, aged 20 who had suffered a football injury eight months previously. He experienced pain below the occiput and limitation of motion of the neck but no paralysis. Roentgenograms revealed anterior displacement of the first cervical vertebra on the second with fracture of the odontoid process. Because there were no symptoms of cord compression at this time a plaster cast was applied and the patient returned home. Following this there slowly developed increasing weakness of the left arm. Neurologic examination previously negative now showed atrophy of both arms with increased reflexes. Roentgenograms revealed no change over the previous examination. Since the symptoms were progressive operative intervention was deemed advisable. Under local anesthesia the posterior margin of the foramen magnum and the arch of the atlas were removed. A cast was worn for six months. A report two years following operation revealed that the patient was perfectly well except for slight stiffness of the neck.

⁵ Elliott C R and Sachs E. Observations on Fracture of the Odontoid Process of the Axis with Intermittent Pressure Paralysis. *Ann Surg* 76: 876-882 (Dec.) 1912.
⁶ Craig W M. Fracture Dislocation of Cervical Vertebrae with Injury to the Spinal Cord. *S Clin North America* 11: 841-852 (Aug.) 1911.

The slow onset of cord symptoms is again seen. Roentgenograms were not taken until some months after the injury, so that the exact position at the time of the original trauma is not known. Decompressive laminectomy alone has been very effective here, but there is still a chance that trouble may develop at a later date.

In an article on fracture of the odontoid process Fritzsche⁷ suggests the possibility of bone graft, quoting de Quervain as having had good results in two cases in which a transplant from the spine of the scapula was utilized. This has found its way into the literature under the subject atlanto-axial dislocation. De Quervain's⁸ cases, however, were fracture dislocations of the fifth or the sixth cervical vertebra.

Foerster⁹ has reported a case of progressive atlanto-axial dislocation in which three months after the initial trauma a tetraplegia developed with severe respiratory symptoms. The arch of the atlas, lamina of the axis and posterior lip of the foramen magnum were removed. A single fibular transplant 13 cm in length was placed between the occiput and the spinous process of the seventh cervical vertebra. The symptoms cleared up entirely.

It is possible that this excellent result was obtained from the laminectomy alone, since it is difficult to conceive of much immobilization as coming from the long narrow transplant itself. The latter was in contact with the cervical spine only at one point, the spinous process of the seventh cervical vertebra.

Juvara and Dimitriu¹⁰ report a case in which a man, aged 29 fell on his head from a tree, and a tetraplegia developed four months later. At operation the arch of the atlas and posterior rim of the foramen magnum were removed. The spinous process of the axis was split. A tibial graft was placed between the occiput and the split spinous process of the axis and was attached to the spinous process of the third cervical vertebra. Death occurred less than twenty-four hours after the operation. Autopsy revealed an old compression of the upper cervical cord with recent hemorrhage in the gray substance.

In the first case we are reporting a somewhat similar procedure was carried out.

CASE 1—E F a Polish youth aged 18 entered the University Hospital July 15 1933 three days after having been injured in an automobile accident. A diagnosis confirmed by x rays was made of compound fracture of the left parietal region and multiple fractures of the mandible. Debridement

Fig. 3 (case 1)—October 10. A Forrester collar has been worn intermittently. Mild symptoms suggesting cord compression are present.

of the skull fracture was immediately performed. Five days later the mandible¹¹ was wired. The patient was discharged August 1, after an uneventful convalescence and was advised to return in a week.

The patient was seen in the outpatient department August 3 complaining only of pain and stiffness in the neck. These symptoms had been present since the injury but were not seriously considered because of the severity of the other injuries.

Examination revealed muscle spasm and limitation of motion of the cervical spine in all directions. The scalp wound was healed. The patient was discharged for another week and returned August 19.

He was now suffering severe pain in the neck and was supporting the chin and occiput in his hands. The head was displaced forward in the typical position of high cervical dislocation. Lateral roentgenograms of the cervical spine showed a forward displacement of the atlas and skull on the axis and a fracture at the base of the odontoid process,

the latter having been carried forward with the atlas. In reviewing the original head films, it was seen that there had been overlooked a fracture of the odontoid process with slight forward displacement of the atlas on the axis. The patient was sent home in a Forrester collar.

October 10 the patient returned to the hospital stating that he had worn the brace only intermittently. The pain had persisted and radiating pain had developed in the right arm. Examination showed marked prominence of the spinous process of the axis. The forward displacement of the head had apparently increased. There was marked weakness of the abductors of the right shoulder. A subjective complaint of numbness in the right upper extremity was not borne out by sensory examination. The deep reflexes of the upper extremities were hyperactive. It was realized and proved by roentgenograms that the dislocation was progressing and that there was undoubtedly pressure on the cord. The patient was placed on a Bradford frame and head traction was applied. The

Fig 5 (case 1) — April 3 1934. Tetra plegia present.

symptoms disappeared almost immediately. A portable x-ray machine, November 30, revealed slight but definite improvement. It was felt that complete reduction by traction was impossible and that closed manipulation would be dangerous. A Forrester collar was again applied and the patient discharged ambulatory December 15.

¹¹ Because of this and subsequent partial ankylosis, roentgenograms were never taken through the mouth and the posterior pharynx was never palpated.

The patient was perfectly well for one and a half months when paralysis of the right side of the body slowly developed, along with incontinence of urine and feces.

He reentered the hospital April 3, 1934, almost completely paralyzed. Neurologic examination revealed no cranial nerve palsies. There was spasticity of all four extremities. The right arm was almost completely paralyzed, the left arm was markedly weakened. The jerks of the biceps and triceps were hyperactive, more so on the right. The abdominal and cremasteric reflexes were absent. The knee and achilles jerks were overactive but equal. There was a bilateral Babinski sign. Analgesia was present from the second dorsal vertebra down but was not demonstrated on the arms. There was diminished vibratory sensation of the right ankle, but sense of motion and position of the toes was normal.

The patient was placed on a Bradford frame with the head in traction but after five days there was only slight improvement in motion of the arms and legs. Accordingly, operation was performed.

Under tribrom ethanol-nitrous oxide anesthesia, a midline incision was made from the external occipital protuberance to the spinous process of the sixth cervical vertebra. The muscles were stripped from the occipital bone laterally starting from the superior nuchal line on both sides, down to the foramen magnum. The spinous processes and laminae of the second,

Fig 6 (case 1) — Oct 20 1934 showing bony fusion.

Bony shelves were turned down from the occipital bone on both sides of the median nuchal crest. A Hibbs fusion was done from the second to the fifth lamina. A graft obtained from the iliac crest was placed on each side of the midline, starting from the superior nuchal line of the occipital line down to the lamina of the fifth cervical vertebra. Multiple bone chips were placed round the grafts. A small triangular piece of bone obtained from the ilium was placed between the occipital bone and the axis to protect the cord from pressure. Care was taken to see that no bone pressed directly on the exposed dura. The wound was closed in layers.

The patient was then immobilized in a plaster cast. The wound healed by primary intention. There was a rapid disappearance of the neurologic symptoms. The patient was allowed up four and a half months after operation. He was soon walking in a Forrester collar. Neurologic examination was now entirely negative except for a bilateral Babinski and Chaddock's sign. The brace was removed seven months after operation after roentgenograms showed evidence of solid bony fusion. Examination at this time showed complete loss of rotation of the head and only a few degrees of flexion and extension of the head on the neck, the motion taking place below the fusion.

The patient returned one year after the operation. He had been working for the past four months as an office messenger. He stated that he felt in no way handicapped by the fusion.

There was from 10 to 15 degrees lateral motion of the cervical spine. There was very slight rotation the motion taking place just below the fusion. The fusion felt solid clinically.

The only abnormal manifestation on neurologic examination was a suggestive left-sided Babinski reflex. The grip was powerful in both hands.

In atlanto-axial dislocation, one should ever bear in mind the possibility of further progression. The shallow broad articulating surfaces with the laxness of the ligamentous attachments between these vertebrae predispose to increased forward slipping when the odontoid process has been fractured.

When symptoms of spinal cord compression develop and are not rapidly relieved by traction, removal of the arch of the atlas is imperative. Foerster's patient with marked respiratory difficulty was undoubtedly saved by immediate operation. It is very possible that in the case of Elliott and Sachs the operation, considered at the time but abandoned because of the patient's respiratory disturbance, might have been successful.

Whether removal of the arch of the atlas alone is always sufficient, as in Craig's case, in which there was freedom from cord symptoms after two years, is debatable. In a case cited by Mixer and Osgood this pro-

cedure recovered completely and a massive bony fusion developed while the other case terminated fatally.

We feel that a graft taken from the ilium has several advantages over a tibial graft. The iliac graft is more cancellous, can be split in two, and is more easily molded to the area of fusion.

CASE 2—D. M., a man aged 20, admitted to the University Hospital Sept. 26, 1934, had been injured in an automobile

Fig. 8 (case 2)—Anteroposterior views. A, Sept. 24, 1934; B, December 20, 1934, showing progression of dislocation more marked over left lateral mass.

accident one month previously. The only symptoms present were pain and limitation of motion of the neck. The neurologic examination was negative.

Roentgen examination revealed a fracture dislocation of the atlas on the axis. A Forrester collar was applied, which relieved all pain.

The patient returned for examination, December 20, without complaints. Roentgenograms showed a definite progression of the dislocation but suggested bony fusion. After a week in head traction, improvement was demonstrated by roentgenograms showing that solid bony fusion was not present. The Forrester collar was readjusted and the patient was discharged.

Fig. 7 (case 2)—A, Sept. 24, 1934; and B, December 20, 1934, showing progression under conservative treatment.

cedure was apparently done, and death occurred suddenly a month later. There is no doubt that solid bony fusion guarantees greater safety.

In the very acute symptoms of pressure myelitis with respiratory difficulty, removal of the arch alone is indicated. The longer, more traumatizing procedure of bone grafting is out of the question at this time but could easily be done at a later date. With the patient in comparatively good condition, we feel that the more radical procedure should be carried out in one stage.

Several points might be mentioned on technique. As the procedure is an extensive one and dead spaces may be left beneath the grafts, there is some danger of postoperative hemorrhage. When only the arch of the atlas is removed preparatory to placing the graft, the danger is minimized by placing a small graft between the occiput and the axis. This minimizes the dead space beneath the large grafts and prevents direct pressure on the cord.

We have performed two other fusions of the cervical spine after extensive laminectomy. In both of these cases postoperative hemorrhage developed though it did not manifest itself in either case until the third day. In both cases the wound was reopened. One patient

Fig. 9 (case 2)—A, Dec. 27, 1934, showing improvement after one week in traction; B, April 23, 1935, again showing failure to maintain improvement in Forrester collar.

He was again seen April 23, 1935, still symptom free. Roentgenograms again revealed increased dislocation. Another trial in traction was suggested to see whether bony fusion in this position was present. This was refused because the patient felt so well and he was discharged in the collar.

Once more the progressive nature of this lesion is shown. A trial was given conservative treatment with the Forrester collar. In spite of the fact that there was symptomatic relief giving a false sense of security to

all concerned, the dislocation has slowly progressed, as shown by roentgenograms. The improvement obtained by traction showed that bony fusion had not taken place. Fusion was advised at this time and refused by the patient. The most recent roentgenograms show that conservative treatment has again failed to maintain the correction.

SUMMARY

Forward displacement of the atlas on the axis with fracture of the odontoid process is a progressive lesion. One should not be lulled into a false sense of security following a symptom-free interval on conservative treatment. During the course of conservative treatment, should evidence of progression be found occipito-cervical fusion is indicated before pressure myelitis develops. In retrospection, fusion was indicated in case 1 at a period shown in figure 4, and in case 2 (fig. 9A).

If pressure symptoms develop removal of the arch of the atlas ordinarily followed by bony fusion of the occiput to the cervical spine, is the treatment of choice.

DIAGNOSTIC GASTROSCOPY

WITH SPECIAL REFERENCE TO THE FLEXIBLE
GASTROSCOPE

RUDOLF SCHINDLER, M.D.

Visiting Professor of Medicine, University of Chicago
CHICAGO

My purpose in this paper is to describe the flexible gastroscope, to discuss the technique of examination with this instrument, and to emphasize its simplicity and value.

The diagnosis of internal disease has always been hampered by the impossibility of seeing the involved organs. The advent of cystoscopy marked a great step forward in the diagnosis of pathologic conditions of the urinary tract. Proctoscopy made a similar contribution to the diagnosis of diseases of the rectum and bronchoscopy likewise to diseases of the bronchi. All attempts to devise a simple and practical method for direct inspection of the interior of the stomach, however, were relatively unsuccessful, owing to the difficult anatomic problems involved, until final success was attained with the perfection of the flexible gastroscope in 1932.

HISTORY

In 1868 Kussmaul,¹ the first to attempt gastroscopy, used a rigid open tube, which he introduced into the stomach of a sword swallower. His efforts were not successful, however, because there was no adequate way of lighting the interior of the stomach. This came only after the development of the Edison electric lamp in 1879. The real development of the method began when Mikulicz in 1881 devised a very ingenious gastroscope. He understood all the problems of gastroscopy as they are known today: the visualization through a long tube of the interior of a large cavity, one of difficult topography and requiring distention by air. Mikulicz² recognized the fact that a straight line usually cannot be made between the teeth and the lower parts of the stomach and, consequently, devised an instrument with an elbow or knee, which he thought would provide for the necessary angle at the cardia. The instrument was, on the whole, like a cystoscope, a closed tube with a

lamp at the end and the objective of the optical system just proximal to the light. There was also an air channel through which air could be blown into the stomach. The instrument was rather large and complicated, perhaps dangerous, and for these reasons Mikulicz apparently gave up his efforts to visualize the interior of the stomach.

Rosenheim³ in 1895 was the next to make an attempt. He found that a long, straight, rigid tube could be introduced into the stomach in many cases and consequently all gastroscopes from that time on were built as straight, rigid tubes. It is now known that this was unfortunate. It was found that in only about 50 per cent of cases was it really possible to reach the lower part of the stomach. As the years passed, better optical systems were perfected and other improvements were made. In 1908 and 1911 the rather effective instruments of Loening-Stieda and Elsner were developed. Chevalier Jackson⁴ tried to eliminate the optical system by working with open esophagoscopic tubes but was only partially successful. A very ingenious development was that of Sussmann⁵ in 1911, who constructed a flexible tube which was mechanically straightened into a rigid instrument after its introduction. It soon disappeared from use, however, because the straightening procedure was very dangerous and the optical system was easily dislocated.

Gastroscopy was practically forgotten from that time until the construction of my first rigid gastroscope in 1922.⁶ This instrument corrected some of the minor errors inherent in the former tubes, but its essential principles were the same. Nevertheless it was the standard instrument for ten years. With it I made over 1,300 gastroscopic examinations and viewed the interior of the stomach in a great variety of diseases. Other examiners reported observations in several thousand additional cases.⁷

There were numerous contraindications to the use of this instrument, such as the presence of a short, thick neck, arteriosclerosis, heart disease, slight kyphosis and scoliosis. Marked resistance to the introduction of the tube was frequently encountered at the cardia. Rupture of the esophagus in overcoming this resistance was quite possible. It was obvious even in the beginning that it would be impossible to employ this instrument in daily clinic use. Further experience verified this early impression and convinced me that this instrument could not be used as a routine procedure.⁸ It was, in my experience, however, superior to and safer than the open tube type of gastroscope but, nevertheless not satisfactory.

Consequently, it became necessary to perfect an instrument which would be flexible from a point about 3 cm. above the cardia to the distal end of the tube.⁹ Roentgenologic studies showed that the distal end should be one which could be bent in two different planes. The solution of this difficult optical and mechanical problem became possible only when it was discovered that a tube

are not discernible. At times a complete atrophy may be seen. The exact relationship between atrophic gastritis, carcinoma, benign tumor, pernicious anemia and achylia gastrica remains to be ascertained.

3 Hypertrophic gastritis. In this condition the mucous membrane is velvet-like and swollen and contains a number of nodules or wartlike excrescences with numerous creases between the elevations. Frequently, very small and superficial ulcers are present. The exact relationship of this condition to chronic gastric and duodenal ulcer remains to be ascertained.

SUMMARY

1 The flexible gastroscope has made it possible to visualize the interior of the stomach with safety and with relatively little discomfort to the patient.

2 The flexible gastroscope affords an additional method for the direct morphologic diagnosis of gastric disease.

3 Gastroscopy not only supplements the roentgen examination in the direct diagnosis of gastric ulcer and gastric neoplasm, but it aids greatly in their differential diagnosis. It also furnishes direct evidence of the progress of the benign lesions and of the degree of involvement in cases of neoplasm.

4 Gastroscopy reveals gastritis and other changes in the gastric mucous membrane not discernible by other procedures.

Clinical Notes, Suggestions and New Instruments

PRIMARY CARCINOMA OF LIVER WITH HEPATOSPLENOGRAPHY

D E EHRlich M.D. AND F C ANSANELLI M.D. NEW YORK

The case we are about to present should be of interest to the medical profession for four reasons: (1) the rarity of the condition, (2) the atypical clinical changes, (3) the interesting hepatography and (4) the necropsy.

Primary carcinoma of the liver is a rare entity both clinically and at autopsy. The lesion is present in approximately one out of 2,000 necropsies. Furthermore primary carcinoma is usually found to inhabit the right lobe of the liver. The following report deals with a primary carcinoma of the left lobe of the liver.

REPORT OF CASE

History—H. M., a white man, aged 70, a laborer, single, admitted to the hospital in April 1934, complained of generalized abdominal pain, anorexia, weakness, loss of weight and the presence of a lump in the left epigastric region. The onset began one year before observation with abdominal pain and fulness after the intake of food as well as intermittent pains in the flanks and epigastrium, loss of weight, general weakness and at the time of admission a feeling of weight in the abdomen. There was a loss of 60 pounds (27 Kg.) from the onset to the time of admission. The only past history of significance was that the patient had been a heavy indulger of alcoholic beverages.

On admission the patient was chronically ill but able to walk around and sit up in a chair. The salient observations in the examination were the pinched features, dullness at the left posterior base of the chest with diminished breath sounds and the abdominal changes to be described. The abdomen was full in the lower epigastric and upper umbilical zones. The overlying skin and umbilicus were freely movable. A mass was palpated between the epigastrium and the umbilicus, slightly movable and located more to the left of the median line. The right liver edge was just palpable and mobility with respiration was questionable at this time. There was dullness and tenderness directly over the mass.

Course—For four months the complaints remained about constant except that the patient suffered more from intermittent abdominal pains in the upper half, and a dragging sensation was felt. During this time he did not have constipation in any degree. At this time examination revealed a more distended abdomen centrally and laterally, a distention of the superficial abdominal veins and a tenseness over the mass. The mass felt more superficial and smooth and measured 8 by 15 cm. vertically and transversely respectively, two thirds being to the left of the median line. The tumor now shaped like an eggplant had definite upper, lower and lateral borders, the upper edge being 3 fingerbreadths below the inner right costal margin, with a tympanic note between the costal margin and the upper border of the tumor. The mass was ballotable mainly to the right and upward, not without considerable pain. Dullness and tenderness were still present over the mass. At this time there were crepitus and fluctuation but no hydatid thrill was present. The right lobe edge was 3 cm. below the

Fig. 1—Barium meal in colon, pressure effect on colon by large liver.

costal margin. The mass did not move with respiration and abdominal respiratory excursions became lessened in depth. A suggestive icteric tinge appeared over the face, conjunctivae and abdomen. In between pains the patient walked about, played a game of cards and conversed until a bilateral bronchitis developed nine days prior to his death. The patient was afebrile and clear of bronchitic signs three days prior to death. He died in September. Constitutional signs during the clinical course prior to the onset of bronchitis were periods of tachycardia, an occasional degree rise in temperature for one or two days and respirations averaging 22 per minute. The blood pressure on admission was 160 systolic, 80 diastolic and near death 122/64.

Laboratory examination revealed the following. The Wassermann test was negative. The blood chemistry was negative on several occasions. The icteric index was normal until near death at which time it was 15. Galactose cholesterol ester tests were of no aid.

A blood count April 2 showed red blood cells 4,200,000, white blood cells 12,600, polymorphonuclear leukocytes 93, hemoglobin 80 per cent. April 18, red blood cells 4,700,000, white blood cells 13,300, hemoglobin 50 per cent. September 2, red blood cells 3,640,000, white blood cells 5,200, polymorphonuclear leukocytes 66, large lymphocytes 34, hemoglobin 85 per cent.

The specific gravity of the urine ranged from 1.010 to 1.016 but otherwise the urine was normal. Examination of the feces was negative for color, ova, increased fat or undigested fiber, pus, blood and the like.

Roentgenograms of the chest showed thickened pleura over the left base. A flat plate of the abdomen showed a soft tissue shadow in the epigastrium, nature unknown and two right abdominal calcified lymph nodes. The gastro-intestinal tract revealed no intrinsic lesion. There was a narrowing of the distal part of the transverse colon suggesting a pressure deformity of an extrinsic nature (fig 1).

Fig 2—Postero anterior view after injection of thorium dioxide. Large liver and spleen with rarefaction in the area of the left lobe.

Hepatosplenography (75 cc of thorium dioxide sol in seven days, with no untoward reactions) revealed marked enlargement of the left lobe of the liver upward and downward the lower border extending to the first lumbar intervertebral disk and slight enlargement of the right lobe. In the upper third of the left lobe were areas of lessened density. In the lower

Fig 3—Lateral view after injection of thorium dioxide sol. Liver and spleen superimposed but distinguishable separately.

two thirds was a well delineated semicircular mass of lessened density. An area of lessened density was found in the right lobe. The spleen was moderately enlarged. There was an incidental visualization of gallstones of which there was no history and of which he never complained (figs 2 and 3).

The clinical diagnoses in order were metastatic cancer of the liver from a primary gastro-intestinal lesion, primary

cancer of the liver, cystic carcinomatous mass of the pancreas and carcinomatous cyst of the mesentery.

The pathologic diagnosis (by Dr Vera B Dalgopol) was primary carcinoma of the left lobe of the liver with a necrotic and hemorrhagic mass protruding over the plane of the liver and its intralobar branches, carcinomatous thrombosis of the portal vein, and cholelithiasis (fig 4).

COMMENT

The foregoing facts of this case may indicate why the tentative clinical diagnoses were made. Here is a case of proved primary carcinoma of the left lobe of the liver, a clinical impression of such being little grounded without the aid of hepatography by thorium dioxide sol. The facts that made a liver diagnosis not too strong were the presence of a well outlined mass with tympany between the upper border and the costal margin, the free mobility, the crepitus and fluctuation and the absence of respiratory mobility. However the unusual necropsy changes, especially of a necrotic and hemorrhagic carcinomatous mass pouchlike with well defined borders, fairly well explain the atypical clinical observations. Then again it is surprising that, with such marked thrombosis of the portal vein by carcinomatous liver tissue there was no ascites but marked compensatory superficial abdominal veins. One will have to be satisfied to assume that the thrombosis of the portal vein was so slow that the venous network was able to compensate gradually for this flow. Yet the age, weakness, loss

Fig 4—Postero anterior view after injection of thorium dioxide sol. Gross specimen liver density changes are more prominent.

of appetite, loss of weight and strength and presence of an abdominal mass were classic in pointing to a carcinomatous process.

Thorium dioxide sol was given as the last means of help in a confirmatory or negative way. The films presented reveal a primary lesion of the liver which together with the known clinical facts add up to a diagnosis of primary liver carcinoma. Without thorium impregnation, similar cases give a history of needless surgery for exploration. Of course, partial hepatectomy is occasionally attempted. However even though rarely there is a successful removal of the diseased part the practice is seldom done owing to the difficulty and dangers of hemorrhage and secondly to the well known sequence of recurrence.

CONCLUSIONS

1 We have presented a case of primary carcinoma of the left lobe of the liver with its atypical clinical observations correlated to and elucidated by the roentgen and necropsy studies.

2 Without the use of thorium dioxide sol there was not enough clinically to strengthen too strong a clinical impression.

3 Thorium dioxide sol, while still debated, has its use in selected cases as a last resort in the diagnosis of liver involvement in abdominal carcinoma. It will aid in determining the operability of the case.

4 This patient would probably not have survived as long as he did had surgical measures for exploratory laparotomy been performed.

5 It is also shown that a complete thrombosis of the portal vein does at times produce no ascites when the process is slow enough to allow gradual venous compensation.

3120 Buhre Avenue, Bronx—27 West Eighty-Sixth Street

MACULAR LEPROSY

REPORT OF A CASE OCCURRING WITHOUT ANESTHESIA

EWELL I THOMPSON MD AND ALBERT DE GROAT MD
LITTLE ROCK ARK

In view of its close resemblance to some of the commoner skin diseases treated by the general practitioner this case of leprosy is reported. It is of general interest because the severe symptoms and usual signs are absent. The confusion with other diseases, the failure of treatment based on this confusion and the method of arriving at a correct diagnosis add further to the general interest of the case. Although the symptoms had been present a year or longer the diagnosis was made relatively early. The absence of anesthesia nodules and alopecia and the presence of a symmetrical, generalized eruption caused various observers to confuse the condition with syphilis pityriasis rosea and dermatophytosis. A generalized lymphadenopathy constituted a final diverting element in the clinical picture.

McCarthy¹ classifies leprosy as follows: maculo-anesthetic, nodular and transitional types. The maculo-anesthetic type usually shows areas of hyperesthesia and signs of neuritis early in the disease. According to Sutton² the great auricular, the ulnar and the peroneal nerves are the first to be involved. The earliest objective cutaneous manifestations suggest a toxic erythema. Apart from a few scattered bullae, which may appear from time to time, the eruption consists of numerous reddish or purplish patches limited for the most part to the face and the extremities. The subsequent evolution of the lesions varies considerably. Some of the patches may fade leaving brownish pigmentations while others may become transformed into plaques and nodules.

Fig 1—Macular leprosy

The lymph nodes are seldom involved primarily, some authors even alleging that the lymphadenopathy is the result of secondary (staphylococcal) infection.

Alopecia is caused by the general toxemia although the eyebrows may be damaged by the local granulomatous process. The general toxemia which marks the stage of invasion is

responsible for the symptoms of fever, headache, joint pains, sweating, weakness and general malaise. Occasionally there is epistaxis.

The mixed type is characterized by macules and nodules. Some of the nodules develop from macules, while others develop independently. The nodules usually contain enormous numbers of bacilli. It has been claimed however, that in the older lesions the bacilli become rare and correspondingly difficult to find. For this reason the differentiation from tuberculosis and syphilis may be complicated.

Fig 2—Lepra cells infiltrating a lymph node

The appearance of macules is usually preceded by anomalies of sensation, such as formication, burning, stinging or itching.³ The size of the lesions varies from that of a 50 cent piece (30 mm) to that of the palm of the hand or even larger. By peripheral extension and coalescence large irregular areas having curved contours are produced. The centers of the macules usually become depigmented and anesthetic. The borders on the contrary may be hyperpigmented and hyperesthetic.

REPORT OF CASE

A white man, aged 35, a native American, entered the clinic of the United States Public Health Service at Hot Springs, Ark., later being referred to one of us by Dr. O. C. Wenger for consultation. The patient presented a generalized itching eruption which had appeared one year previously. For three months there had been numbness in the hands, indigestion, loss of appetite and loss of about 15 pounds (6.8 Kg.) in weight. For this condition he had received antisyphilitic treatment. Questioned concerning his past history, he stated that while in an army camp at San Antonio, Texas, in 1918 he had had an eruption which he believed resembled the present one. The personal and family histories were otherwise essentially negative.

The physical examination revealed a generalized macular, varnish brown to reddish brown eruption most marked on the anterior surface of the trunk and on the flexor surfaces of the arms. No lesions were noted on the penis, the palms of the hands or the soles of the feet or in the mouth, nose or throat. The macules were round or oval and varied in size from 0.3 to 1.5 cm. They were moderately smooth and nonindurated.

J. Orm by O. S. A Practical Treatise on Diseases of the Skin for the Use of Students and Practitioners, 4th Philadelphia, Lea & Febiger, 1934.

¹ McCarthy, Lee, Histopathology of Skin Diseases, St. Louis, C. V. Mosby Company, 1931.

² Sutton, R. L., Diseases of the Skin, St. Louis, C. V. Mosby Company, 1928.

Although the lesions gave the impression of being elevated, this could not be confirmed by palpation. The symmetrical distribution and the tendency to follow the tension lines of the

Fig. 3—Lepra cells infiltrating the corium

Fig. 4—A nodule in the subcutaneous tissue

skin indicated a systemic origin. There was neither scarring nor pigmentation from past lesions. The lymph nodes, particularly those of the inguinal group, were enlarged, reaching

a maximum diameter of 3 cm. They were firm but neither tender nor painful. There was slight thinning of the skin on the dorsal surfaces of the hands, which the patient had first noticed several months previously. The physical examination was otherwise negative.

The laboratory reports were as follows: erythrocytes 4,000,000; hemoglobin 80 per cent; leukocytes 9,400; neutrophils 53 per cent; stab cells 4 per cent; juveniles 1 per cent; lymphocytes 38 per cent; eosinophils 4 per cent. The Wassermann, Kahn and Kolmer tests of the blood were negative. The urine was normal. Smears from the nose showed acid fast bacilli varying from curved rods about the size of a tubercle bacillus to short rods which were almost coccoid.

The report on a biopsy of specimens from the cutaneous lesion and a lymph node was as follows: The structure of the lymph node was profoundly altered by an extensive infiltration of large polyhedral cells having an abundant clear cytoplasm

Fig. 5—Intracellular and extracellular lepra bacilli in a lymph node

and small vesicular nuclei. The cytoplasm of most of the cells was finely vacuolated but in some a single large vacuole displaced the nucleus to one side. In places germinal follicles remained and these contained many cells which were undergoing mitotic division (fig. 2).

The skin (figs. 3 and 4) showed thinning of the malpighian layer with partial effacement of the papillae. Immediately beneath that layer were numerous compact collections of polyhedral and spindle cells which resembled in all respects the large vacuolated cells found in the lymph node. They occurred chiefly about the blood vessels where they often formed perivascular sleeves which could be followed for some distance. A few discrete collections were located deep in the corium.

Sections (both skin and lymph node) stained by the Ziehl-Neelsen technique revealed acid fast rods which varied greatly in size and thickness. Many of them were arranged in packets (fig. 5). Some were beaded, others solid. Most of these bacilli occurred in the large clear cells previously described.

SUMMARY AND CONCLUSIONS

1. An atypical case of macular leprosy was observed which closely resembled syphilis, pityriasis rosea and dermatophytosis.
2. Sporadic cases of leprosy may occur in native Americans without known exposure to the disease. Because of this fact

the variations in the early manifestations of leprosy should always receive consideration in the differential diagnosis of obscure cutaneous diseases

3 Macular leprosy may exist for at least one year without clearing in the center of the lesions, formation of nodules or much extension

4 In the early cases the diagnosis can be made with certainty only by means of a biopsy with demonstration of the organism

GLANDULAR PHYSIOLOGY AND THERAPY

THERAPEUTIC APPLICATIONS OF INSULIN

ELLIOTT P JOSLIN, M D

WITH THE COLLABORATION OF

HOWARD F ROOT, M D

PRISCILLA WHITE, M D

AND

ALEXANDER MARBLE, M D

BOSTON

NOTE.—This article and the articles in the previous issues of THE JOURNAL are part of a series published under the auspices of the Council on Pharmacy and Chemistry. Other articles will appear in succeeding issues. When completed the series will be published in book form.—Ed

Every one requires insulin, and if a person cannot manufacture what he needs in his own pancreas he is fortunate if he can secure it by purchase or gift. No one, the normal person or the diabetic patient, knows the quantity required to maintain health and strength. Fortunate it is that nature regulates the supply with surprising accuracy, balancing its production with the carbohydrate consumed, whether this is for prompt utilization or for storage, and adjusting its output to the momentary demands of exercise or rest. This normal regulatory mechanism rarely may go awry and too much insulin may be produced, in fact, so much may be secreted that at times death results from hypoglycemia. Probably at other times every one experiences symptoms from an increased production of lesser degree, which he recognizes in himself by hunger and fatigue and which his friends suspect by his altered disposition. But it is difficult to decide whether these states are actually due to too much insulin or to deficient carbohydrate through lack of body glycogen.

Insulin is susceptible to many influences. If the supply of insulin is sufficiently curtailed or possibly if its efficiency is impaired by overaction of pituitary, thyroid or adrenals diabetes mellitus results. Lowering of the alkalinity of the blood, infections, starvation or an excessively high fat diet also affects its action adversely, but not strikingly enough to prove that any of these bring on diabetes. The development of diabetes in the obese focuses attention on the possible effect on insulin production of the constant stimulation of the insulin-producing function of the pancreas in order to assimilate the carbohydrate consumed, but it seems hardly likely that the pancreas would be injured in this way, because there is no analogy to this in the field of other ductless glands. Although it is true that a diet high in fat and low in carbohydrate decreases insulin pro-

duction, as shown repeatedly by many investigators, nevertheless such a diet, when carried out in the Du Bois laboratory for over a year on two human beings, temporarily lowered carbohydrate tolerance, but did not do so permanently. It is remarkable that, whatever agency injures the pancreas, it practically never wholly destroys the ability of the gland to make insulin. Clinical experience confirms physiologic experiments on this point, diabetes is not complete. Obviously this complicates enormously the problem of the therapeutics of insulin, because one never knows how much insulin the active pancreatic remnant yields and therefore how much must be supplied. Just as in health there is reasonable certainty that the production varies under different conditions, so too one can infer that it varies in diabetes. Therefore in the administration of insulin it must always be recognized that one is dealing with a variable, and results must be interpreted cautiously and with extreme deliberation.

The variable course of diabetes makes difficult the interpretation of the action of insulin. This variability in the course of diabetes was emphasized by Naunyn. Of course, he did not actually say that the secretion of insulin was increased or decreased, but he described most clearly the improvement in the condition of the patient who carefully followed dietetic treatment and the reverse in those who neglected it. Today still more clearly is one convinced that, if the diet is extreme in any direction, ultimately the pancreatic function deteriorates. Insulin increases greatly the chance of the diabetic patient to improve, and one sees in increasing numbers patients whose nutritional state has advanced so much with diet, exercise and insulin that diet and exercise alone suffice. Paradoxical as it sounds, the statement is true that the use of insulin enables many a diabetic patient to do without it. Probably no physician appreciates how high this percentage can rise. John in his manual has taken the pains to record a long list of patients who have given it up, and his experience can be duplicated by many others.

Miss P, who had had diabetes for twelve years, with onset at the age of 50, and was bedridden with rheumatoid arthritis, took daily for years a diet of 1,600 calories containing approximately 180 Gm of carbohydrate, with 80 units of insulin to maintain her weight and aglycosuria. She died of endocarditis and pericarditis. The pancreas, which weighed 15 Gm, was the smallest encountered by Shields Warren in 367 autopsies on diabetic adults. How many units of insulin Miss P's pancreas produced daily it is useless to conjecture, but presumably not many.

Miss M, on Aug 7, 1922, was the first patient to whom I gave insulin. Thus I considered to be my most severe case of diabetes. The patient's tolerance was estimated as about 7 Gm of carbohydrate. The patient, now 54, has had diabetes for 17 1/2 years, she has gained to 137 pounds (62 Kg) from her erstwhile 69 pounds (31 Kg) leads an active, useful life, takes 130 Gm of carbohydrate, 1,688 calories, and is nearly aglycosuric with 44 units of insulin a day. If Miss P, like Miss M, had been able to have the advantage of exercise, very likely her insulin need would have been halved. These two cases suggest that an adult requires between 80 and 45 units of insulin daily, von Holm's experiments would substantiate this opinion. When, therefore, patients say that they require more than 80 or even 50 units, I suspect a complication such as an infection, acidosis, glandular disease, hemochromatosis or just

plain ignorance or carelessness in the quantity and quality of the diet. This went to such extremes in the daily life of one patient that actually less or at least no more insulin than she was accustomed to take daily on her own account was sufficient to bring her out of diabetic coma while under hospital supervision.

EFFICIENCY IN THE USE OF INSULIN

To attain maximum efficiency in the use of insulin, its continuous administration would be necessary. Only thus would one imitate nature, which regulates the insulin supply according to the carbohydrate demand of the hour, nay, even of the minute. The Toronto workers early pointed out the advantages of the multiple over the single dose. The more frequently insulin is given, the less is required to produce the same result. Von Holm showed this beautifully with depancreatized dogs. With a constant intravenous injection of insulin, Bertram calculates from von Holm's experiments that a normal adult of 60 Kg requires 78 units per day when fasting and 48 units when living on a diet the caloric value of which is composed exclusively of carbohydrate.

One dose of insulin a day will suffice for many a diabetic patient perhaps for half of those who require

TABLE 1—*The Dietetic Treatment of Seven Groups of Thirty Cases Each of Diabetes**

Group	Date	Age at Onset Years	Carbohydrate Gm	Protein Gm	Fat Gm	Calories per kg	Insulin Units	Weight Kg
I	1915	40	26	54	76	18		57
II	1916	46	43	60	82	21		56
III	1917	42	43	60	90	23		54

V	1927	40	96	60	113	28	21	59
VI	1931	43	144	68	90	29	21	68
VII	1933	40	153	73	91	29	26	60

* Joslin E. P. A Diabetic Manual ed 5, Philadelphia Lea & Febiger 1934 p 60, table 6

it, but the severer the disease the more frequent should be its administration. Ordinarily a dose of insulin exerts an action for eight hours. In infections one resorts to injections of insulin every six, four, three or two hours, and in coma in which the need is extreme and the demand for efficiency in action the greatest, it is often injected every thirty minutes.

When one dose of insulin per day suffices, it is usually best to give that before breakfast, if two doses are necessary, doses are given before breakfast and supper. If these doses reach the level of from 20 to 40 units each and are still inadequate to control glycosuria, then three or four doses a day may be advisable. Often, particularly with young persons who have severe diabetes, it will be found helpful to give the third dose at bedtime, i. e., from 10 p. m. to midnight. By so doing one decreases the tendency for the blood sugar to rise in the early morning hours, and an adequate dose at bedtime may enable a patient with severe diabetes to awake with a sugar-free urine. The late evening dose is usually given without food and must be relatively small, 2, 4 or 6 units, in order not to provoke hypoglycemia. Some patients require a dose of insulin before each of the three meals plus the bedtime dose. We have not thought it advisable to give insulin "by the clock," i. e., every six, eight or twelve hours, regardless of meals, because of the danger of producing hypoglycemia. Some clinicians do advise and use such a method, however.

THE ACTION OF INSULIN

Insulin lowers the percentage of sugar in the blood and favors its storage and utilization in the liver, muscles and skin in the form of glycogen. As a result, calories are conserved, not lost, and acidosis is prevented, and thus the processes of metabolism function normally. Occasionally the action of insulin is so great that the blood sugar is lowered below the normal level and a whole train of phenomena arise, dependent in part on the low blood sugar per se, the lessened glycogen in the tissues or the excess of protective counter-regulatory processes set in motion to raise the blood sugar. The combination of all these processes is known as an insulin reaction, or insulin shock. The harmful effects of a low blood sugar are emphasized so often that I wish to point out first of all how such a condition may be advantageously utilized. When the blood sugar drops, the counter-regulatory mechanism of the body, through stimulation of the sympathetic system, tends to relieve the resultant hypoglycemia by favoring the discharge of glycogen from the liver. If this counter-regulation goes too far and the liver glycogen is depleted unduly, the liver acts less well in furthering carbohydrate metabolism. Under such conditions even acidosis is said to occur, just as it does as a result of uncontrolled diabetes when the liver is deprived of glycogen and is filled with fat. This state of an approaching depletion of glycogen in the liver can be forestalled by the administration of carbohydrate, and if this is done at such a time, i. e., when the blood sugar is already low and falling, apparently it is very well tolerated, so well in fact that the favorable phenomenon has been noted by patients. They frequently report that if at the first sign of an insulin reaction they take carbohydrate, it is tolerated so well that it counts as a pure addition to the carbohydrate allowance, and they need not deduct it from the subsequent meal. In treating coma, if the blood sugar is reduced to 0.05 to 0.08 per cent often for twenty-four hours, carbohydrate is utilized remarkably well, with little or no insulin.

AVERAGE DOSE

The average daily dose of insulin taken by the insulin-treated diabetic patient is probably about 30 units. This dosage is rising rather than falling, first, because the quantity of carbohydrate in the diabetic diet has been steadily going up throughout the country, and, secondly, because the proportion of patients with severe diabetes is much greater, particularly children and young adults, who owe their preservation to insulin. For one diabetic child who formerly survived ten years I suppose there are 100, and perhaps 1,000 today.

How Many Grams of Carbohydrate Will One Unit Metabolize?—This question no one can answer. There are always adjustments required for exercise and diet. Even if these two factors are constant the improvement of the condition of the patient overthrows one's calculations. Then too there are many complications in diabetes that affect the clinical potency of the unit. In diabetic coma several units may be necessary for the utilization of 1 Gm of carbohydrate, but, as acidotic symptoms subside, 1 unit of insulin becomes more efficacious. The crippling effect of infections on the power of insulin is well known. Other factors are discussed under the section entitled Insulin Resistance. In general, the value of a unit decreases with the number given and follows the law of a diminishing return for the power expended, as with a gasoline engine. The first

ten units is more effective than the second ten, and so on. There is another factor insulin cannot act with greatest efficiency unless given an opportunity to display its power. An orator needs an audience to show what he can do, and insulin needs carbohydrate. Thus it has been shown repeatedly by those inaugurating the higher carbohydrate diet that the carbohydrate can be doubled with little or no additional requirement for insulin, provided total calories are controlled. But I am still somewhat skeptical. In table 1 are recorded comparable groups of thirty diabetic patients with their diets and insulin dosage, representing as a matter of fact the insulin dosage used in my clinic over a series of years. The figures show no tendency to an increase in the carbohydrate equivalent of a unit, and no increase for the total dextrose. I confess that I do not understand why these groups of my patients do not show a greater carbohydrate equivalent for 1 unit of insulin. All will agree that the whole human machine works better when a substantial amount of carbohydrate is being burned and that carbohydrate and fat metabolism profit by avoidance of either extremely low or extremely high respiratory quotients. Exceptionally there may be no lack of carbohydrate to burn, but it may be in a form that is not combustible. Thus, plenty of carbohydrate may be administered in the diet to a patient with hemochromatosis, but because the glycogen storage facilities of the body are impaired, particularly in the liver and skin (perhaps also in the muscles) insulin may not find any glycogen on which it can act. This is only one of the many states in which insulin is not blamable. In general 1 unit of insulin will metabolize 1 or 2 Gm of carbohydrate, and perhaps even from 3 to 6 Gm, Newburg even says 7, but it is impossible to say definitely, because one never knows how many units the patient's pancreas is producing each day or at the moment. Therefore it is dangerous to prescribe insulin in arbitrary or schematic fashion, in general the method of trial and error should be adopted, always erring on the side of low and frequent rather than of high and single dosage. Whenever I read that for each gram of dextrose lost in the urine or given intravenously 1 unit of insulin should be injected, I shrug my shoulders and exclaim *Prenez garde!*

METHODS FOR ADMINISTRATION OF INSULIN

Many methods for the introduction of insulin into the body other than by the needle, subcutaneously or intravenously, have been tried and found wanting and do not merit discussion in this article. Theoretically, aside from the disadvantages of puncturing a vein, one would expect the intravenous route to be more effective than the subcutaneous, but it has been discarded, perhaps to an unjustifiable extent, because a portion of the insulin introduced is excreted in the urine. For this reason even in coma we always give insulin subcutaneously whenever we give it intravenously. To avoid the necessity of frequent injections of insulin attempts have been made to administer it in oil at infrequent intervals. These too have failed.

If insulin is given in the superficial layers of the skin, it is said to be more effective than when injected into the deeper layers. How true this is I do not know. At any rate one avoids the superficial layers because if insulin is so injected it is apt to give rise to insulin burns or blisters, owing to the mechanical effect of the solution injected.

Site of Injection—The site of an injection of insulin should be changed so frequently that not more than one dose is given in the same spot in a month. Children, partly from their desire for routine, prefer no alterations in location, and also partly because frequent injection in the same area destroys the sensibility of the skin and subcutaneous tissue. When so administered the insulin is poorly absorbed and its effect to a greater or less degree nullified. Furthermore, infections at the site of injection may result more easily. Recently an uncontrolled fat diabetic girl showed abscesses in the upper part of the thigh, where she asserted no insulin had been injected. Although she very likely spoke the truth, these probably did follow the introduction of insulin, the infection having spread along the lymphatics, an explanation that has been suggested for insulin atrophies occurring at a distance from the point of injection. For convenience it is well for patients to construct an insulin map of the body on which points of insertion for the needle for a month can be recorded, and thus surely one can avoid duplication of site. Another ruse to capture the attention of the patient is to say "Use the right leg in the morning, the left leg at night and follow a line down the anterior aspect of the leg for a week, moving outward to a new line each succeeding week of the month."

Other localities for insulin injection include the arms particularly the deltoid and triceps regions, the upper, not the lower portions of the buttocks, and the abdominal wall. In the last-named situation, needles shortened to three eighths of an inch can be employed. The needle best liked by my patients is half an inch long and 26 gauge.

Insulin Prescriptions—Orders for the giving of insulin can be expressed simply. Most patients and nurses understand that 10—0—0 signifies ten units before breakfast, 15—0—10 means 15 units before breakfast and 10 before the evening meal, and 20—10—15—2 indicates insulin before each meal and also on retiring. These are orders for definite doses, but such cannot be employed during infections and coma and usually after operations. Under such circumstances one can use the formula $\frac{R \ Y \ G \ B}{15-10-5-0}$ in which 15—10—5 or 0 units below the line are to be given according to the red, yellow, green or blue results of the Benedict test, expressed above as R, Y, G, B, the qualifying time period in hours can be added—thus, every 6—4—3—2—1— $\frac{1}{2}$ hours. Obviously the range in the number of units can be altered to meet the requirements of the individual case or of an emergency. In coma, particularly the time interval is frequently revised, during a half day this may be changed from every half hour to every one, two, three or four hours, according to the progress of the case.

Measuring Insulin—The danger of confusion in measuring the dose of insulin is real. Patients fail to comprehend that a unit is a unit and that whereas 1 cc of U-10 insulin contains 10 units, 1 cc of U-20 insulin contains 20 units, 1 cc of U-40 insulin contains 40 units and so on up to U-100 and more. In order to guard against errors it is well to verify the patient's dosage at each visit. Even a clergyman and a doctor make mistakes, and patients who have taken insulin over a period of years are just as likely to be wrong in their reports as those just beginning. Partly for this reason, the simplest type of syringe is desirable and this I have found to be one marked only with divisions into

tenths of one cubic centimeter. We now use almost entirely the 40 unit strength, thus reducing the volume of fluid (insulin) required at an injection.

Time for Injection of Insulin—The maximum effect of an injection of insulin occurs in an hour, in contradistinction to that of the peak effect of food on the blood sugar, which takes place in half that time. Neither statement is absolute, the latter particularly is subject to variation. Absorption from the digestive tract is so irregular that our surgeons do not countenance the administration even of such simple liquids as orange juice, water oatmeal gruel or ginger ale within three and even four hours before the time of an operation, for fear of the patient vomiting on the operating table. And, since the adoption of this plan, I am told by the nurses that patients tolerate food after operation more satisfactorily. The blood sugar is often higher before and rises higher after breakfast than before and after the other meals, hence insulin is given at a longer period before breakfast. This period is most commonly thirty minutes but may be increased to forty-five or even sixty minutes. Convenience is an indication that often lessens the interval to fifteen minutes or less at noon and night.

The Sabbath was made for man and not man for the Sabbath and this must not be forgotten when dealing with insulin. Patients are ingenious and intelligent and often devise the ways and means best adapted for the management of their own cases. It is a good thing to allow them considerable latitude. There should be no regimentation in diabetes, the physician should seek to develop the individual's initiative.

CONTRAINDICATIONS

Insulin Anaphylaxis—Localized anaphylactic phenomena develop frequently about the area of injection when treatment with insulin is begun. In a few days, rarely as long as a few weeks of repeated injections, it is the rule for these allergic manifestations gradually to disappear. They were far more common when insulin was first discovered, presumably owing to impurities with protein. Should these local areas of sensitization fail to disappear or plainly grow less within two weeks, it is well to change to insulin made from another animal, or it may suffice to use insulin prepared by another pharmaceutical firm. In no case have we been obliged to give up or even to consider giving up treatment of a diabetic patient with insulin on account of such phenomena.

Insulin Lumps—Under "site of injection," attention was called to the harmfulness of repeating injections of insulin in the same area. As a rule, tumefactions result and, if the injections are long continued, necrosis of the subcutaneous tissue occurs. Such tissue is more readily susceptible to infections and, in fact, about the only infections one sees as a result of the use of insulin take place in such regions. Obviously, insulin given in such an area is poorly absorbed, it was pathetic to hear a patient say that he always took his insulin in a given area, where, as a matter of fact, there was a tumefaction, because if he injected elsewhere he would bring on a reaction! Therefore, patients should be impressed that, if insulin is scattered, less insulin will be required.

Insulin Atrophies—Insulin atrophies are far more annoying, disfiguring and more permanent than insulin anaphylactic phenomena or insulin lumps. These occur

as a rule at the exact site or near the site at which insulin has been administered. In contrast to insulin lumps, which are tumefactions of the skin and subcutaneous tissues as a result of repeated injections in one place, areas of insulin atrophy are characterized by depressions of the surface of the skin with almost complete disappearance of the subcutaneous fat and some times of muscle tissue also. Usually these depressions on the surface of the body are replaced within a year if these regions are avoided in the course of treatment, but occasionally they persist for a much longer time. They are deforming and the physician should include in the routine visit of the diabetic patient to his office search for these and for insulin lumps, just as he checks the insulin dosage and inspects the patients' feet, lungs and tongue, and carries on his regular physical examination.

The cause of these atrophies is not known. It is evidently not due to the antiseptic tricresol, which at one time was used in the preservation of insulin. It does not appear to be due to injury of muscular tissue. Indeed, occasionally the atrophic areas are remote by several centimeters from the point at which the insulin was injected. We have seen what we considered to be such areas on the face when all possibility of a connection with local injections seemed out of the question. It is plausible to conclude that the areas may develop at a considerable distance from the site of actual injection by transference along the lymphatics, but it is difficult to explain by this theory these facial areas. These areas are not alone disfiguring, they may rarely be so extensive as to render the continuance of treatment a matter of difficulty. They occur in children and adults, in both sexes, and exceptionally in patients whose diabetes is controlled. Similar atrophies are reported sometimes to follow the use of other glandular extracts, such as posterior pituitary extract.

The treatment of insulin atrophies resolves itself into their prevention. There is no treatment for them when formed. Such patients must exercise scrupulous care in their selection of needles and in deft insertion of them. High strengths of insulin are preferable, such as 80 or 100 units per cubic centimeter, in order to reduce the volume of fluid injected. Patients have been advised to change from pig to beef insulin or vice versa and to try one preparation on one half of the body and the other on the other half, but thus far no satisfactory conclusions have been reached. Insulin atrophies make a pretty problem for research. Their solution might unlock the door to many other problems of fat metabolism.

INSULIN REACTIONS

Overdosage of Insulin—Symptoms of an overdosage of insulin, for practical purposes, are identical with those resulting from a fall in the percentage of sugar in the blood below normal. Often they are said to develop when the blood sugar is at a normal level or even above. Such instances have not come to the personal attention of the authors of this article, and we subscribe to this statement, realizing fully that a few excellent clinicians hold an opposite opinion. It is certainly true that sudden falls of the blood sugar from high levels to levels only slightly below 0.10 per cent (100 mg per hundred cubic centimeters of blood) give rise to symptoms of a reaction that would never be felt under ordinary conditions. Confusion occurs in the patients' minds regarding an insulin reaction when they

note the characteristic symptoms and yet find the urine loaded with sugar. They do not realize that the glycosuria they have demonstrated by their Benedict test represents sugar that passed through the kidneys hours or at least minutes previously and then was retained with the urine in the bladder. In a true reaction a second freshly passed specimen of urine will be found to be sugar free, provided the bladder was thoroughly emptied at the previous micturition.

When a diabetic child becomes quiet, lacks interest and is unnaturally good, when a diabetic adult acts ambitionless, depressed and morose, or an elderly man or woman weak and faint, I wonder if their blood sugar has fallen below normal. Very likely they are hungry but do not know it. If the occasion is some hours after meals, particularly if they have had an active period of exercise and I learn that they took their usual dose of insulin and in haste ate less than usual, I feel reasonably sure that my guess is correct. And the surmise changes to certainty if I find a tremor in the hands with moisture in the palms and a few beads of sweat on the forehead. Diabetic patients in such a condition respond to questions like an automaton and somehow give the impression that soon they may become unconscious or, quite the reverse, become emotionally unstable. Dilated pupils, firm rather than soft eyeballs, diplopia, pallor rather than a red face, normal respiration and blood pressure, and normal or sometimes rapid pulse nearly complete the picture, which, if unchecked by the taking of carbohydrate, may end in complete unconsciousness followed by convulsions. The latter state may last for hours and infrequently end in death—the result of an overdose of insulin leading to a severe insulin reaction with extreme hypoglycemia.

Hypoglycemia with signs such as these constitutes the picture of an insulin reaction to all in this clinic, and we expect its relief with the giving of 5, 10 or more grams of dextrose. No patient has died of an insulin reaction at the New England Deaconess Hospital, but three of our patients, living many miles away and not under our care, and two others seen in consultations have succumbed. One, a young girl, was found unconscious as the result of a reaction which the attending physician mistook for diabetic coma, she was given 200 units of insulin and failed to recover consciousness in the course of thirty-six hours. Another patient, a young man, similarly succumbed after 60 units. The third patient, a child, died after an exhausting illness when the apathy, extreme weakness and unconsciousness were ascribed to the illness and left untreated. The diagnosis in the last case was missed in an excellent clinic partly because sympathy for the child delayed a venous blood sugar test (at that time a method for a capillary blood test was not available). Recently a fourth patient, a school teacher, returned to her home at 6:30 p. m. and behaved queerly. When a physician arrived thirty minutes later she was unconscious and having convulsions. Unable to obtain a urine test, he diagnosed coma and gave 200 units of insulin during the night. The next day, the hypoglycemia was recognized and treated with intravenous dextrose until the blood sugar was well above normal, but she died. In a fifth case hypoglycemia developed every afternoon because the physician tested the blood sugar only before breakfast and increased the insulin dose each day because the fasting blood sugar was high. This patient recovered consciousness with 10 Gm of dextrose given intravenously, lapsed one hour later and again recovered with a second

such injection. One hour later she again lapsed into unconsciousness and died when dextrose injection was delayed. The prognosis of an insulin reaction is almost invariably good if it is diagnosed reasonably early. Recognition is vital, as the foregoing cases show. For this reason table 2 is inserted, because it contains the salient points of differential diagnosis between an insulin reaction and diabetic coma.

Treatment of Insulin Reactions—Treatment of an insulin reaction is simple, 5 or 10 Gm of dextrose orally usually relieves the patient in a few minutes. Occasionally three times as much is required, and sometimes it is necessary to inject the dextrose intravenously, in which case as a rule the response is so prompt that before 10 cc of a 50 per cent solution is introduced recovery has occurred. The longer the duration of an insulin reaction and the deeper the unconsciousness, the more carbohydrate is required, in one of the fatal cases seen in consultation, 200 Gm of dextrose was given.

TABLE 2—History, Symptoms and Signs Differential Diagnostic Points Between Diabetic Coma and Insulin Reactions*

	Diabetic Coma	Insulin Reactions
1 Onset	Slow days	Sudden minutes
2 Food	Too much	Too little
3 Insulin	Too little	Too much
4 Presence of an infection	Usual	None
5 Thirst	Extreme	Absent
6 Hunger	Absent	Frequent and extreme
7 Vomiting	Common	Seldom
8 Pain in abdomen	Frequent	Absent
9 Fever	Frequent	Absent
10 Skin	Dry	Moist
11 Tremor	Absent	Frequent
12 Vision	Dim	Double
13 Appearance	Florid extremely ill	Pale weak and faint
14 Respiration	Exaggerated (air hunger)	Normal
15 Mental state	Restless and distressed gradually approaching unconsciousness	Apathetic, irritable hysterical gradually approaching unconsciousness
16 Urine sugar	Present	Absent or always absent in the second of 2 specimens
17 Response to treatment	Gradual improvement in hours with insulin	Sudden improvement in minutes with carbohydrate by mouth and rectum intravenously or subcutaneously

* Joslin E. P. A Diabetic Manual ed 5 p 126 table 14

intravenously and subcutaneously before the blood sugar began to rise.

If the patient will not swallow, dextrose can be introduced into the esophagus by catheter through the nose. We have known no harm to result from this procedure, but we have been told of liquids having been forced on patients during a reaction and entering the lungs. Dextrose, syrup, molasses and honey have all been used. Syrup diluted with twice its volume of water can be given by rectum, but its efficacy is questionable.

Various substitutes for dextrose, such as levulose and cane sugar, have been tried, but none are quite as good. Of course, for the mild group of symptoms that accompany a slight lowering of the blood sugar, carbohydrate in any form, and I dare say even protein, might suffice.

Epinephrine will mobilize dextrose in the blood provided its precursor, glycogen, is available in the body. Consequently one can give to an adult, in a reaction that has occurred not too many hours after a meal, 1 cc of 1:1000 solution of epinephrine subcutaneously or half this dose for a child. But even if the injection of epinephrine is effective, it should be followed by the intake of carbohydrate, because otherwise the recovery might be only temporary.

EDUCATION OF THE PATIENT IN THE USE OF INSULIN

The education of the diabetic patient is a *sine qua non* to the successful use of insulin, but he will never receive the full benefit of it unless he is faithful to his other two therapeutic aids, diet and exercise, and lives an honest diabetic day. It is surprising how well insulin works, even when intelligence and common sense are feeble and ignorance profound, but it is certainly true that the faithful patient who knows the most about his disease lives the longest. After thirty-six years of interest in diabetic patients (for half of that time, perhaps one third to one half of my practice has been devoted to diabetes) I can say most emphatically that the diabetic patient whose course of treatment is guided by clinical symptoms in conjunction with and not independently of laboratory tests is the one who does the best, gets the most out of life, and suffers the fewest complications.

Education of a diabetic patient by books and pamphlets accomplishes much, but class instruction does more, because it drives home the salient features of treatment. The questions and answers that arise in the classroom leave more indelible impressions than the written word. One can explain to a diabetic class the danger of a diabetic patient using alcohol, and it carries far more weight than if said alone to that individual in the class who needs this advice the most. The simpler the questions of the members of the class and the more intimate the disclosures of their own experiences with insulin, the better for all. In diabetic camps education is easy, because it is promoted by contact and acquired involuntarily. Supplementing class instruction is the painstaking tutoring of patients by the teaching diabetic nurse in the hospital or the visiting diabetic nurse in the home. Our diabetic classes are now attended more than ever and our plans for daily individual instruction steadily increase. These statements apply I am sure everywhere in the United States and therefore I have no hesitation in making them. All this must be so, because the expense of diabetic treatment must be reduced.

DURATION OF LIFE OF THE MODERN DIABETIC PATIENT

The diabetic patient who acquires his diabetes today will survive four times as long as did the diabetic patient in the first fifteen years of this century, and perhaps longer. Therefore the plan of the campaign to control diabetes must be arranged for a long period and not for a short one. This becomes increasingly apparent, because many of the diabetic patients who are discovered today were overlooked formerly, the period between onset of the disease and diagnosis has been shortened and therefore, as a rule, the cases are of a milder character.

OCCASIONAL DANGER OF DIABETIC DIET

It is impossible to explain the therapeutics of insulin without reference to the diabetic patients' diet. The diet in and of itself can be dangerous to some diabetic patients. With the extremely low carbohydrate, high fat diets of a generation ago, we literally drove many diabetic patients into coma, and many of those who avoided immediate death later acquired arteriosclerosis. Careless dieting, on the other hand, also had its victims from ensuing loss of strength and weight and increased

susceptibility to infections. Incidentally, one judges only of the efficiency of a type of treatment, no matter what its character, by the course of its faithful and intelligent followers and not by that of the ignorant and careless. Dietetic treatment lays only if adjusted to the age, weight and occupation of the patient. Even the rapid reduction of weight of a fat diabetic patient may expose him to so high an endogenous fat diet as to produce acidosis, and with that a lowering of the efficiency of both endogenous and exogenous insulin.

Delayed Absorption of Food—A Menace to an Insulin-Treated Diabetic Patient—The absorption of food by a diabetic patient is not always according to Hoyle, even if the food is quantitatively and qualitatively correct. Too often the patient and the physician conclude that food given reaches the circulation at once, and insulin is administered on that supposition. Our experience with our surgical patients, as I have already said, taught us the contrary. Food, even soluble food, may remain unabsorbed in the digestive tract for long periods with disastrous results to the patient who has taken his dose of insulin. Emotion is the chief cause for the delay and therefore emotional states must be avoided at meal times by all diabetic patients. One of the severest reactions in the literature was that recorded by Millard Smith in a child who had just eaten a full meal but did not absorb it, and until she vomited it left her doctors in a quandary.

INSULIN IN RELATION TO EXERCISE

Exercise tends to lower the blood sugar in the diabetic patient in whose body there is an adequate supply of insulin, whether this is of endogenous or of exogenous origin. This effect is so striking and so beneficial that exercise along with diet and insulin is now accorded a definite and prominent place in the everyday treatment of diabetes. Patients themselves recognize and make use of the principle. Unless an accompanying condition contraindicates activity, diabetic patients should not be kept in bed but rather must be encouraged to take regular, daily exercise. Through muscular activity, food tolerance improves and higher diets with smaller dosages of insulin are possible. This is most strikingly shown in the much lower insulin requirement of diabetic children while in summer camps as compared with the larger need during the winter when they are in school and relatively inactive. The "insulin reaction" that may follow unusual or strenuous exercise in the well controlled diabetic patient is a matter of common knowledge.

Before insulin became available in 1922, clinicians had recognized that, whereas patients with milder grades of diabetes profited by exercise, those with severe or poorly controlled diabetes were made worse. This is undoubtedly correlated with the fact that when, at the time of the exercise, the diabetic patient is deficient in insulin, muscular activity causes a rise and not a fall in blood sugar. This can readily be demonstrated by allowing a patient with moderately severe or severe diabetes to exercise in the morning before insulin or breakfast has been given. Determinations made at frequent intervals during and following the exercise under such conditions will show that the immediate effect is a definite rise in blood sugar. If a small dose of insulin is then given, further exercise causes a greater fall in blood sugar than would be expected from the insulin itself. There is some evidence to indicate that

in certain patients the taking of food may so stimulate bodily insulin secretion that postcibal hyperglycemia may be lowered by exercise following the meal. Here also, however, the endogenous insulin supply must undoubtedly be of a certain adequacy for this effect to be secured.

The practical application of such studies is clear. Not only must patients with diabetes of higher grades of severity receive insulin but, if at all possible, they must exercise regularly. The insulin dosage must be large enough to maintain a well controlled diabetic condition and then this regular exercise will exert its maximum benefit.

The favoring effect of exercise on the utilization of carbohydrate and the lowering of the blood sugar must be borne in mind whenever insulin is prescribed. As a rule the dose of insulin outside the hospital should be less than that in the hospital, and it is usually wise to reduce the insulin allowance of a patient when he is discharged.

Improvement of the diabetes and along with it of the general condition of the patient will take place with almost any kind of intelligent diabetic treatment if faithfully followed. With insulin the possibilities for improvement have been greatly augmented, and such gains both doctor and patient must be alert to recognize. Tolerance for carbohydrate may advance so rapidly that insulin reactions occur needlessly, frequently the need for insulin disappears. The physicians who advocate and prescribe insulin most freely are naturally the ones most frequently to reduce and omit it. Insulin is insurance during an infection, patients should learn how they can take advantage of this insurance when the emergency of an infection arises. Undoubtedly many persons started on insulin are allowed to drop it, and the older the patient the higher the percentage. It is known that, when many old diabetic patients die, the symptoms of the diabetes have so far subsided that even the word "diabetes" does not appear on the death certificate. With children, reduction in the quantity of insulin often is accomplished safely but its omission is seldom permissible.

The danger of rapidly becoming sugar free was recognized before the discovery of insulin by changes resulting from an alteration of the water balance of the body. Disturbances of vision would follow and it would require an interval of one or two weeks before they would clear. With insulin the same symptoms may occur and it is common for the patients to complain of failing eyesight, which one must urge them not to attempt to rectify immediately with glasses. Generalized edema is a far more troublesome complication, it is due largely to retention of water accompanying the storage of carbohydrate. As a rule it disappears of itself, but this can be hastened by restriction of salt and by the use of diuretics.

INSULIN IN DIABETIC COMA

The introduction of insulin has lowered the incidence of the mortality from diabetic coma in the total diabetic mortality (authors' series) from 60 per cent in the years from 1898 to 1914 to less than 5 per cent in a recent compilation (1930-1933). Insulin has reduced the mortality of diabetic coma itself to 11.9 per cent. In children under 15 years the mortality of diabetic coma (authors' entire series) was 1.3 per cent (seventy-eight attacks), in adults above the age of 20 years it was 20.5 per cent (thirty-two deaths in 156 cases).

The mortality in the very old, surprisingly, was somewhat lower than in those of middle life. In the last forty-nine successive cases of diabetic coma treated there has been one death.

Coma is the crucial test of the efficacy of insulin or, indeed, of any diabetic remedy. But the use of insulin in coma can never be by rule of thumb. One patient will recover with 780 units, and another may recover, or at least has recovered, with 28 units. How, therefore, shall one proceed with the dosage of insulin when confronted with a case of diabetic coma?

The principles underlying the treatment of diabetic coma are four: (1) promotion of the utilization of carbohydrate by the use of insulin, because in this way the acidosis is most effectively corrected, (2) correction of the dehydration that is invariably present, (3) protection of the circulation (a) by maintenance of a glycogen reserve in the heart through the administration of insulin and carbohydrate and (b) by the correction of an abnormal mineral balance by supplying sodium chloride and water, subcutaneously and intravenously, in order to prevent renal block and anuria, (4) relief of a dilated stomach by lavage and of obstipation by enema.

How many units of insulin should one give at the first dose? To answer this question requires careful thought. The more recent the onset of the diabetes, the shorter the duration of the symptoms of the acidosis, the less severe their character as measured by the carbon dioxide of the blood, the greater the freedom of the patient from complications, notably infections, the better the condition of the circulation and especially the more nearly normal the blood pressure, and the less subnormal the temperature, the less is the amount of insulin required. Therefore, our rule is to give insulin at intervals of thirty minutes instead of in one large dose, because this allows time for the study of all the circumstances attending the development of the coma. Often the treatment of the complications plays an important factor indirectly by lessening the severity and shortening the duration of the coma.

Usually the first dose of insulin is between 20 and 40 units, but it may be as low as 5 units or as high as 100 units. If the circulation is obviously poor and sluggish and the temperature subnormal, a duplicate dose of insulin is injected intravenously, and the extremities are massaged and other measures are employed to raise the temperature of the body to normal. The initial dose is repeated almost invariably in half an hour, but after that at half-hour, hourly or less frequent intervals as indicated by the change in the patient's symptoms and signs, as indicated by mental clarity, respiration, and especially by the blood pressure, and by the changing volume of carbon dioxide in the blood, the percentage of blood sugar, the volume of urine and its content of diacetic acid and sugar. As soon as one detects a favorable response to treatment, the quantity and frequency of injections of insulin are decreased, one is alert to prevent a fall of blood sugar to a hypoglycemic level and avoids this by administration of carbohydrate. The second and third twelve-hour periods in the recovery of a case of coma demand close attention, because too easily will the patient revert into the coma state. To obviate this the urine or blood must be examined at least every two or three hours at first and later every four hours, diet and insulin dosage must be adjusted accordingly.

Various authors give one large dose of insulin at the inception of the treatment of coma, believing it to be more effective. Some authors give dextrose, 1 Gm per insulin unit, to prevent insulin reactions and to allow more carbohydrate to be burned and thus more rapidly to overcome acidosis. We have felt it more desirable to treat the disease diabetes rather than the condition acidosis and to give carbohydrate only when the disease is coming under control and tolerance for carbohydrate is being reestablished. We have felt that our 293 cases with 11.9 per cent total mortality, our single death among seventy-eight attacks in children and only one death in the last forty-nine coma cases justify adherence to our present methods. As for alkalis, they have not been administered by us since 1917 and we know of no evidence that would warrant our resuming their use. Others who have used alkalis in the past have reduced the dosage that they originally prescribed from a hundred or more grams first to 50 then to 30 and then to 20, below which, it is acknowledged even by a former advocate of alkalis they can have no material effect. Yet one finds lingering in the books recommendations that the stomach be washed out in coma with a 5 per cent solution of sodium bicarbonate and that a few hundred cubic centimeters be allowed to remain in it, or with still less a scientific basis that an enema be administered and 10 or 15 Gm of sodium bicarbonate be retained, of the latter we know that but little will be absorbed.

The liberal use of physiologic solution of sodium chloride, always slowly administered, subcutaneously, intravenously, seldom rectally, will offset the dehydration and help to protect the blood pressure. Occasionally, for the latter purpose, 50 mg of ephedrine sulphate may be introduced dissolved in the saline solution, or 1 cc of 1,000 epinephrine hydrochloride may be added to each 500 cc of the salt solution. Not once in the course of treatment of 293 cases of coma have we seen the heart embarrassed by the volume of saline solution, which at times has reached 4 or 5 liters in the course of twelve hours. When premonitory signs of anuria have appeared or even actual anuria, it has been possible in several instances to bring it to an end by the intravenous injection of 40 cc of 10 per cent solution of sodium chloride once or twice in eight hours. Perhaps transfusion will avail, but of that we have some doubt and little experience.

For the maintenance of glycogen in the heart muscle we depend on insulin, but when the blood sugar begins to fall, and at any rate within twelve hours of the commencement of treatment, we give carbohydrate orally (ginger ale, orange juice or water oatmeal gruel not over 100 cc an hour) or dextrose intravenously, planning to keep the carbohydrate at about 150 Gm in twenty-four hours.

It seems necessary to make these statements about the treatment of coma because they represent measures that must go on simultaneously with the use of insulin.

Always with a diabetic patient in coma the physician should watch for the coincidence of pulmonary tuberculosis or for its development within the subsequent three years, as Root found in 8 per cent of our cases.

The commonest causes of coma are breaking the diet, the omission of insulin and the development of infections. Breaking the diet is needless, but the development of infections often is unavoidable. As for the omission of insulin, it is true that nearly one fourth

of those who begin insulin later can omit it, but insulin should never be omitted without watching the effect on the urine. It is more essential to teach a patient with diabetes to test the urine when he is not taking insulin than when he is taking it.

Nausea, vomiting and diarrhea are serious in diabetes and can lead both to diabetic coma and to an insulin reaction. If a diabetic patient goes long without food, acidosis develops as in a normal individual, hence diabetic patients should never go long without eating. Temporary fasting for twelve hours more or less may be advantageous, but today no one, I believe, would wish to prescribe a fast for a longer period. In severe diabetes with nausea, vomiting or diarrhea, the lack of food leads to acidosis, the lack of water to dehydration, and if to these two factors is added the omission of the insulin on which the patient's life has depended for years, the onset of coma can be prompt. Conversely, if as a result of nausea and vomiting the meal that has been preceded by insulin is lost, it is easy to understand that the blood sugar may fall too low and an insulin reaction ensue. Consequently, no matter what the status of a diabetic patient, he should not go long without food and I therefore say to my patients "Never stop eating and as long as sugar shows in the urine never stop insulin, and whenever in doubt about the interpretation of symptoms, err on the side of taking soluble carbohydrate such as the coma diet of ginger ale, water oatmeal gruel and orange juice." These rules hold for sea sickness for periods both before and after surgical operations, for infections of all kinds, and for confinements.

INSULIN IN THE OLD AND YOUNG

In the very young and in the very old, insulin should be begun with small but frequent doses. To the old this is particularly reassuring, and later gratifying, when they see that the doses have been reduced from three to two, often to one and frequently omitted altogether. They soon learn that insulin means insurance for them in time of need and become thankful that they have learned about it. The young, at the onset of their diabetes, and the old respond quickly to insulin, and by the use of frequent small doses one escapes reactions which at the beginning of treatment one desires to avoid in these two age groups especially. Not uncommonly diabetic children respond so well to treatment with diet and insulin that one is puzzled to know whether they really do have diabetes after all. In such cases, months are necessary to clarify the diagnosis. And in elderly persons persistence in a suitable dietetic regimen with insulin yields such excellent results that it is easy to overdose the patient.

INSULIN IN HEART DISEASE

An unfounded prejudice exists against the use of insulin in heart disease. It is true that it is of serious concern to lower unduly the sugar in the blood supplying the heart muscle. In diabetes the glycogen content of the heart muscle is high in contradistinction to that of other muscles in which it is low. Presumably in the heart of a diabetic person the glycogen is high to protect it and to make it as easy as possible for this organ to function properly under varying conditions. Be that as it may, it is an incontrovertible fact in our experience that patients with incompetent hearts have been benefited rather than harmed by the use of insulin. Never have

we seen any reason to withhold it in reasonable doses. Knowing the necessity for avoidance of hypoglycemia, we always include sufficient carbohydrate in the diet, change diets slowly and begin insulin in small doses. Thus, in commencing the treatment of an old man with 5 per cent glycosuria, I began with 3 units of insulin before lunch and before dinner and advanced to 5 units before each meal the next day, if with slight increases in insulin it takes a week for such a patient to become sugar free, I do not begrudge the time spent, and I am confident that the damaged heart will be all the better for the insulin. As a matter of fact, this patient improved so much in a few days that I discharged him with 5 units once a day.

INSULIN RESISTANCE

The reporting of cases of insulin resistance or insulin refractory diabetes is now becoming about as uncommon as did that of acute fulminating diabetes after the introduction of undernutrition by F. M. Allen and the improvement in diabetic procedure which that method wrought. Soon after the introduction of insulin it developed that insulin resistance did not exist in children, and little by little it was found out that, after eliminating one complication after another, no adult with uncomplicated diabetes remained who belonged in this category. Before even harboring the thought of insulin resistance one should investigate and be absolutely sure that diet, blood sugar tests, collection and analysis of urine, as well as the quantity and quality of insulin, are as stated and that the insulin is injected in previously untraumatized sites, so that it will be absorbed. If all these requirements are fulfilled, the overwhelming majority of all insulin resistant cases will vanish. Next, one excludes inactivity or destruction of the glycogen reservoirs through lack of muscular exercise, as in passive bed rest or arthritis, through disease of the glycogen-holding cells of the liver, as in hemochromatosis, and again in various disorders of the skin, some of which are as simple as sunburn. Then renal glycosuria is ruled out, and this is not as easy as it seems, I confess to have overlooked this diagnosis in one case for nine years along with competent doctors in two other cities. Frequently in gangrene with an arteriosclerotic basis and in arteriosclerotic disease of the heart and kidney there occurs for a time what appears to be insulin resistance, just as high blood sugars persisted in such cases even before the discovery of insulin, but just as formerly, and now more rapidly, after the removal of the gangrene these cases respond when dietetic treatment is adequate and prolonged. Overfunction of pituitary, thyroid or adrenal may tend to counteract the effectiveness of insulin, but such states are very different from true insulin resistance. It is not always easy to detect hyperactivity of one or another of these ductless glands and should this not be detected when existent, the case seems most obscure. One patient required 32 units of insulin and lost weight until a substernal thyroid was found, but with its removal all need for insulin vanished so completely that it required a sugar tolerance test some months later to disclose that the diabetes was not actually cured. Infections of all sorts lead to insulin resistance and at present the evidence points to the destruction or neutralization of the exogenous or endogenous insulin rather than to lack of insulin formation. Last of all comes acidosis and in its presence resistance is manifest disappearing rapidly with its relief.

INSULIN IN NONDIABETIC STATES

Although little is known concerning the effect of insulin on the carbohydrate metabolism in nondiabetic persons, certain observations indicate that it has a field of usefulness, particularly when undernutrition is a problem. A temporary loss of carbohydrate tolerance during the administration of insulin has been noted in certain patients and also in experimental animals. However, in Blotner's studies the tolerance always returned to normal. Various explanations for this temporary glycosuria, on the ground of a change in the permeability of the glomerular membrane, an increased rate of absorption from the intestinal tract, or a temporary decrease in pancreatic function have been offered, but none seem to have been generally accepted.

Thin, undernourished individuals whose emaciation is due to poor appetite can be helped to take more food. The practice of using insulin in nondiabetic patients to increase weight began in 1923 and was soon adopted for nondiabetic tuberculous cases. The mode of its action is not entirely clear. Insulin is only one of many factors influencing appetite and nutrition, and not all patients with tuberculosis react to its use in the same way. F. M. Allen advised beginning with 5 units three times a day and increasing to 40 units three times a day. The protection against shock depends not so much on large quantities of carbohydrate as on the repeated administration of such small amounts as 10 Gm. Occasionally much larger doses of insulin were given. Individualization of the dosage should be emphasized, especially in cases in which tuberculosis of the adrenals or liver is present. In such cases dangerous hypoglycemia may occur. Gains in weight of 60 pounds (27 Kg.) or more in a few months together with improvement in strength and spirits frequently are reported and are said to be maintained after insulin is stopped. However, all writers agree that insulin is an adjunct and is not to be substituted for any of the regular forms of treatment for tuberculosis.

Renal glycosuria should not be treated with insulin. The fundamental characteristic of renal glycosuria is the constant occurrence of glycosuria even with a normal blood sugar, irrespective of the amounts of carbohydrate ingested. Therefore if insulin is given without study of the blood sugar under a misapprehension of the nature of the glycosuria, the dose may be increased to dangerous levels at which severe hypoglycemia will develop.

HYPERINSULINISM

Under the title hyperinsulinism have been grouped an increasing number of cases of "hunger" disease (Seale Harris) or spontaneous hypoglycemia. The symptoms of hunger, nervousness, sweating, fainting, epileptiform convulsions and unconsciousness, usually relieved by food or by dextrose given intravenously, are due to the hypoglycemia, whether its cause is truly oversecretion of insulin or, as in some instances, a disease of the liver or adrenals. The variety of nervous and mental symptoms as well as cardiac and abdominal symptoms, makes the condition an important one for internist and surgeon alike to bear in mind.

The pathology of the condition has been studied at operation and after death. Hyperplastic islet cells have been found at autopsy in two children (cited by Harris) and in a physician cited by Mosenthal. In some cases at operation normal appearing pancreases have been found. Adenomas and carcinomas of the islets of Langerhans have been shown to produce even in

their metastatic lesions large amounts of insulin (Wilder) It must be remembered that hypoglycemia may occur in certain types of hepatic diseases, in diseases of the pituitary, thyroid and adrenal glands (especially Addison's disease), and Harris urges the study of all other possible causes of hypoglycemia before the diagnosis is made of hyperinsulinism in epileptic patients

The diagnosis may be made tentatively from the clinical symptoms, and from the relief of mild symptoms by frequent carbohydrate feeding and a high fat diet Blood sugar values below 0.06 per cent following a dextrose tolerance test should be watched, especially since in some cases epileptiform seizures have occurred when the blood sugar fell to 0.05 per cent Such attacks may be produced by giving test doses of insulin, but this procedure is not advised

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT

HOWARD A. CARTER Secretary

CENCO THERMELOMETER ACCEPTABLE (Electrical Thermometer)

Manufacturer Central Scientific Company, 1700 Irving Park Boulevard, Chicago

This temperature recording instrument is especially adaptable for taking the temperature of a patient receiving fever treatments

The Thermelometer makes use of two sets of thermo-elements or thermal junctions, one set of two in series being contained in the heat sensitive element, the other or reference junction being located in a sealed chamber, the temperature of which is held constant to within 0.01 degree F. A difference in temperature between the two sets of thermal junctions produces a potential difference, which is impressed across the terminals of a micro-ammeter calibrated to read from 95 to 110 F in one-fifth degree divisions thus corresponding to a clinical thermometer. A heat sensitive junction is confined in a tube connected to a long heavy insulated wire and it is suitable for taking rectal temperatures

Cenco Thermelometer

An electro-finished aluminum case contains all necessary parts except the heat sensitive element, which is removable. A removable metal cap protects the thermoregulator head and reference thermometer. Toggle switches on the front of the case control all electrical circuits, and a "bull's eye" with pilot light behind it affords a visible indication that the instrument is operating. A magnifier above the temperature scale facilitates quick readings. A substantial leather strap makes the Thermelometer readily portable. Its shipping weight is 75 pounds

This unit was tried out in a clinic acceptable to the Council, and the investigations substantiated the claims made by the manufacturers pertaining to its accuracy. The unit seemed rugged and well made and has been under observation for over one year. The unit is not accurate when the fever treatments are given by short wave diathermy units

In view of the favorable report, the Council on Physical Therapy voted to include the Thermelometer in its list of accepted devices

REPORTS OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
PAUL NICHOLAS LEECH Secretary

IMBAK PREPARATIONS NOT ACCEPTABLE FOR N N R

Imbak is the group title applied to a series of several non-descript preparations distributed by Ernst W. Abicht of New York and manufactured by Deutsche Imbak Gesellschaft of Frankfurt-on-Main, Germany. Apparently Imbak (numbers 1, 2, 3, 6 and 10) is some sort of bacterial preparation derived from the lactic acid-forming group. It enjoys the same type of absurdly uncritical promotion typical of many products of foreign origin that have been and are being marketed in this country (some of which have been the subject of Council reports in the past, e.g., Iodo-Mangan, Sulfuryl Monal, Colloidine, Quicamphol, Pinnecksin, Hermal, Atychol, Valamin, Tersul, Hiller, Promonta, Iodeol, Borosedine, Tryptoserm, Eubetin, Antiopin, Propeptans, Naodine, Edwenil). Of course, there are also worthy foreign preparations which have been presented by those who understand what constitutes evidence of an acceptable character to gain the confidence of the American physician.

Imbak was presented to the Council by Ernst W. Abicht of New York, whose main business seems to deal with paper converting machinery. All of the varieties are stated to consist of "only pure natural products, free from all artificial chemicals." The process of manufacture is described

By means of a special procedure, which is protected in all civilized countries, lactic acid bacteria according to Meitschnikoff's prescription are developed in best pure milk of the Alps, and all other superfluous or even damaging microbes exterminated [sic]

No other statement of composition is submitted, nor, in fact, is there any mention of dosage or mode of administration recommended. Deficient though the submission may be in these respects, the therapeutic claims are far from modest. One or the other of the numerical modifications (and here the correlation between a given disease group and the corresponding "number" of the Imbak line indicated therein is frequently not apparent) are recommended in the treatment of the following conditions: intestinal and pulmonary tuberculosis, typhoid, dysentery (amebic as well as other forms), psoriasis, arthritis deformans, arteriosclerosis, diabetes, cholera, malaria, trypanosomiasis, syphilis, "and some more."

The value of Imbak in these various disease states allegedly has been attested to by Prof. Dr. Kessler of the Tung Chu University, Shanghai, and Dr. med. A. Stein, doctor of the State Penitentiary Hospital, Frankfurt-on-Main. Prof. Dr. Kessler has not applied the product to as widely diverse fields of medicine (and surgery) as Dr. med. A. Stein, but he claims to have obtained beneficial results in rickets, intestinal catarrh, constipation and "dyspepsy." Dr. Stein, however, seems most enthusiastic (although apparently proportionately less critical than Prof. Dr. Kessler) in his statements

CANCER

"With regard to cancer it has been possible during the last two weeks [italics ours] to treat two cases notwithstanding it is very difficult to persuade patients to undergo a new cure which has not yet come into publicity also in this case it has been shown in a most evident fashion that justly these diseases which hitherto have caused the greatest difficulties to doctors were extinguished [sic] in a few weeks. The results up to now obtained with the different patients who partly are still under treatment is highly promising, so that already this day we can affirm that at last we have in our hand this means which act directly on the different causes of diseases destroying them. This invention is to be put in the same line which the salvarsan occupies as the Therapia Magna Sterilisans

It would, indeed, promise a glorious era in medicine were such an omnipotent preparation produced, but in this case clinical, pharmacologic and therapeutic evidence to support even a small fraction of the claims is totally lacking, and in consideration of the rather extensive knowledge already established concerning the lactic acid-forming organisms it appears questionable that such properties, even in a small part, may ever

be properly attributed to Imbak or to any similar product, irrespective of the regrettably premature predictions of Prof Dr Kessler and Dr med A Stein

The Council declared Imbak and the submitted dosage forms not acceptable for New and Nonofficial Remedies because Imbak is a semisecret preparation marketed under a noninforming name (rules 1 and 8), promoted with unwarranted and absurd therapeutic claims (rule 6)

This proposed report was submitted to the manufacturer. The firm applied for reconsideration and submitted additional information on the products. The Council considered this information to be wholly inadequate as evidence for acceptability. The firm states that Imbak has many forms in addition to numbers 1 to 10. Number 37 and numbers 40 to 75 are claimed to be useful in the treatment of typhoid fever, tuberculosis, diabetes, obesity, asthma, bronchitis, arteriosclerosis and other diseases. The Council held that this additional material serves only to confirm its declaration of the unacceptability of Imbak.

Committee on Foods

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION AND FOR GENERAL PROMOTION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION

MINNESOTA BRAND AMBEROLLS— ELBOW MACARONI

MINNESOTA BRAND ELBOW MACARONI— AMBEROLLS

MINNESOTA BRAND LONG MACARONI

MINNESOTA BRAND LONG SPAGHETTI

MINNESOTA BRAND MACARONI ALPHABETS

MINNESOTA BRAND MACARONI RINGS

MINNESOTA BRAND MACARONI SHELLS

MINNESOTA BRAND SPAGETS—ELBOW SPAGHETTI

MINNESOTA BRAND VERMICELLI

Manufacturer—Minnesota Macaroni Company, St. Paul

Description—Macaroni of various shapes prepared from durum semolina.

Manufacture—Durum semolina is kneaded with water under corrugated steel rolls, forced through dies containing holes of appropriate diameter and shape to form the various types of macaroni, partially dried and packaged

Analysis (submitted by manufacturer) —	per cent
Moisture	10.0
Ash	0.7
Fat (ether extraction method)	0.9
Protein (N × 5.7)	13.6
Crude fiber	0.6
Carbohydrates other than crude fiber (by difference)	74.3

Calories—3.5 per gram, 99 per ounce.

Claims of Manufacturer—Complies with the United States Department of Agriculture definition and standard.

PETER PAN SLICED SANDWICH BREAD

Manufacturer—Cottons, Inc. Baton Rouge, La.

Description—Sliced white bread made by the sponge dough method (method described in THE JOURNAL, March 5, 1932, p 817), prepared from flour, water cane sugar powdered skim milk, lard, yeast, salt, condensed milk and a yeast food containing wheat flour, sodium chloride, calcium sulphate, ammonium chloride and potassium bromate, malt extract syrup, and corn and soya bean flours

BOB WHITE BRAND FANCY TABLE SYRUP GOLDEN

Manufacturer—The Torbitt & Castleman Company, Inc., Louisville, Ky

Description—Table syrup a blend of corn syrup (90 per cent) and refiners' syrup (10 per cent)

Manufacture—Corn syrup, prepared as described in THE JOURNAL, March 5, 1932, page 817, and refiners' syrup, which complies with the United States Department of Agriculture standard for that product, are mixed in the stated proportions, heated to 70 C and automatically packed in air tight cans

Analysis (submitted by manufacturer) —	per cent
Moisture	24.0
Ash	0.9
Fat (ether extract)	0.0
Protein (N × 6.25)	0.2
Reducing sugars as dextrose	32.6
Reducing sugars as dextrose after inversion	38.7
Sucrose	5.8
Dextrins (by difference)	36.2
Titrateable acidity as HCl	0.03
Sulphur dioxide as SO ₂	0.001
pH	5.6

No methods are available for accurately determining the composition of syrups of this nature, therefore the foregoing analysis is roughly approximate

Calories—30 per gram, 85 per ounce.

Claims of Manufacturer—Recommended for use as an easily digestible and readily assimilable carbohydrate supplement to milk in infant feeding and as a syrup for cooking, baking and the table

WILSON PURE TOMATO JUICE

Distributor—Ira Wilson & Sons Dairy Company, Detroit

Packer—The Loudon Packing Company, Terre Haute, Ind

Description—Tomato juice in bottles, retains in large measure the vitamin content of the raw juice used, contains a small amount of added salt. The same as Loudon Brand Tomato Juice (THE JOURNAL, June 25, 1932, p 2289)

1 BOHACK'S GRAPEFRUIT

2 HALE'S PRIDE FANCY GRAPEFRUIT

Distributors—1 H C Bohack Company, Inc., Brooklyn and Long Island, N Y 2 Hale-Halsell Company, McAlester, Okla

Packer—Dr P Phillips Company, Orlando, Fla

Description—Canned sliced Florida grapefruit sweetened with added sucrose and retaining in large measure the original natural vitamin content, the same as Dr P Phillips Florida Fancy-Cut Grapefruit Slices (THE JOURNAL, Nov 19, 1932, p 1781)

DURKEE'S VEGETABLE OLEOMARGARINE

Manufacturer—Durkee Famous Foods, Inc., Chicago, Norwalk, Ohio, and Berkeley, Calif

Description—Margarine prepared from hydrogenated refined cottonseed oil, pasteurized cultured milk, salt, derivative of glycerin, and sodium benzoate (0.1 per cent)

Manufacture—Hydrogenated refined cottonseed oil is heated to 41-43 C and churned with pasteurized cultured milk. The resulting emulsion is solidified by spraying into a vat of ice water, worked to remove excess moisture, blended with salt, cultured milk, derivative of glycerin (emulsifying agent), and sodium benzoate, cooled to 17 C, molded into prints, and automatically wrapped and packed in cartons

Analysis (submitted by manufacturer) —	per cent
Moisture	14.8
Ash (other than sodium chloride)	0.1
Sodium chloride	3.4
Fat (ether extract)	80.1
Protein (N × 6.25)	0.4
Lactose	0.5
Sodium benzoate	0.1
Glycerin derivative	0.5

Calories—7.2 per gram, 204 per ounce.

SATURDAY, AUGUST 3, 1935

EFFECT OF CHOLECYSTECTOMY ON HEPATIC AND RENAL FUNCTION

Although much information is available regarding the functions of the gallbladder, there are still certain phenomena apparently related to the activity of this structure that remain unsolved. Particularly is this true in the case of certain metabolic disturbances that may follow the removal of the gallbladder, most notable among which are alterations in hepatic and renal function. At first thought it seems improbable that the mere removal of the gallbladder, a structure known to be nonessential to mammalian life and presumably functioning chiefly in the concentration and storage of bile, should exert any deleterious effects on other organs. However, instances of serious postoperative morbidity and even death following simple cholecystectomy have been described in patients who were apparently in good condition before operation. The most careful preoperative examination may fail to reveal any significant hepatic or renal functional impairment, cholecystectomy may be performed without undue trauma, the anesthesia may not produce noticeable untoward effects and still the patient may show evidence of profound functional disturbances, particularly of the liver and kidneys, and may die within a few days after operation.

Questions naturally arise concerning the nature of the hepatic and renal changes following cholecystectomy. The majority of the experimental studies dealing with hepatic alterations have been concerned with the morphologic aspects of the problem. Recently, however, variations in the functional efficiency of the liver have been followed.¹ Simple cholecystectomies were performed on a group of sixty patients with cholecystitis, there were no obstructions of the common duct and the subjects were not clinically jaundiced. Nitrous oxide and ether infiltration or spinal anesthesia was employed, in no case was the common duct manipulated, nor were other operative procedures performed. All the patients were in good clinical condition before

and during the operation, and there were no fatalities. As indexes of liver function, the bilirubin content of the serum and the degree of retention of bromsulphalein were determined.

The data obtained indicated that in the majority of cases there is a slight transitory increase in serum bilirubin and in the retention of the dye, suggesting a temporary impairment of the excretory function of the liver. The increase in serum bilirubin was more constant in cases that did not show preoperative hyperbilirubinemia, the degree of dye retention, however, appeared to bear no constant relation to the extent of the preoperative or the postoperative bilirubinemia. Patency or occlusion of the cystic duct appeared to be of importance in determining the incidence of these postoperative functional abnormalities. Hyperbilirubinemia and increased retention of bromsulphalein were observed in a large majority of the cases in which there were patent cystic ducts, whereas these changes occurred in relatively few of the group showing obstruction of the duct. The probable explanation for this difference is that physiologic compensation, as described by an earlier investigator,² to the lack of functional activity of the gallbladder had already occurred in the latter group. The postoperative increases of serum bilirubin and retention of dye eventually disappeared in every case, although in some instances one or the other persisted for as long as four days. An explanation of these results is difficult. Apparently the effects of the anesthetic were of relatively little importance, as no correlation existed between the duration and type of anesthesia and either the incidence or the severity of the postoperative changes. It is possible that the effects observed may be related to an alleged decrease in the rate of flow of bile following cholecystectomy. Such a change would undoubtedly favor the retention of bilirubin and of bromsulphalein.

Impairment of renal function following cholecystectomy has also been repeatedly observed. Patients with chronic cholecystitis and apparently normal renal function have been known to develop profound uremia following operation. Careful examination of the kidneys of these patients at necropsy frequently reveals a marked necrosis of the tubular epithelium, with focal hemorrhages and patchy areas of leukocytic infiltration. The appearance of the kidneys is distinctly different from the appearance of these organs in biliary nephrosis. Recent histologic studies³ on the kidneys of patients with calculous cholecystitis who died following operation have yielded further confirmatory information, distinct regressive cellular changes in the renal tubular epithelium were observed. Several hypotheses have been advanced to explain these phenomena. One postulates that the renal damage may be due to the toxic

effect of split protein products from damaged, autolyzing hepatic tissue, these toxic products are then supposed to exhibit an elective affinity for parenchymatous and vascular tissues, producing angiospasm and progressive degeneration and necrosis of the tubular epithelium. Neither this nor other theories, however, satisfactorily explain the pathogenesis of all the renal changes following cholecystectomy.

The foregoing unsolved problems regarding functional impairment of the liver and kidney following simple cholecystectomy emphasize again the complexity of interrelations of organs and also the fact that alterations in the activity of one body tissue are frequently reflected by compensatory changes in remote and often unexpected places.

A CRYSTALLINE PROTEIN HAVING THE PROPERTIES OF A VIRUS

The nature of viruses has been a matter for speculation since Iwanowski¹ demonstrated in 1892 that the infective agent causing the mosaic disease of tobacco plants could pass through a porcelain filter. This was the first known virus. Iwanowski's work was confirmed independently by Beijerinck². Loeffler and Frosch³ in 1898 showed that the causative agent of foot and mouth disease also is filtrable through a porcelain candle. Since then more than a hundred filtrable agents belonging to the class now known as viruses have been demonstrated to cause disease in plants and animals.

Many difficulties beset the efforts of investigators to determine the nature of viruses. Some have held that they are living organisms, in view of the fact that viruses do not propagate except in the presence of living tissue and because of their behavior in other respects, some have suggested that these infective agents are nonliving poisons.

The recent announcement made by Stanley⁴ of the Rockefeller Institute is therefore of great importance. Stanley has reported the separation from the juice of Turkish tobacco plants infected with the mosaic disease of a crystalline protein that has the properties of tobacco-mosaic virus. The material was obtained in the form of fine needles, which contain 20 per cent of nitrogen and 1 per cent of ash. The substance is precipitated by a variety of protein precipitants, it is practically insoluble in water but is soluble in dilute acid, alkali or salt solutions. In all respects it behaves like a typical protein.

The crystalline substance produced typical tobacco-mosaic disease on inoculation into tobacco plants, the activity of the crystals was more than 100 times that

of a suspension made by grinding up the leaves from diseased plants. The infectivity, chemical composition and optical rotation of the crystalline protein were unchanged after ten successive crystallizations. Collodion filters through which the protein did not pass also did not permit the infective agent to pass. The newly isolated compound was held back by collodion membranes through which proteins such as egg albumin passed readily, this and other experiments indicate that the molecule of the crystalline protein is very large, having a molecular weight probably of a few million. The protein was inactivated by heating to 94 C, a temperature at which the virus is also destroyed.

The serums of animals injected with tobacco-mosaic virus gave a precipitate with solutions of the crystals in dilutions up to 1:100,000, this did not occur with the serums of animals injected with the juice of healthy tobacco plants. Conversely, injection of solutions of the crystals into animals produced precipitins against the crystalline protein and against the juice of infected but not against that of normal plants.

Stanley regards the tobacco-mosaic virus "as an autocatalytic protein which, for the present, may be assumed to require the presence of living cells for multiplication."

It is too early to speculate on the eventual significance of this fundamental contribution, with regard to its relation to virus diseases in animals or to other virus infections of plants. The concept of nonliving poisons propagated by or in the living cells which are attacked by the poisons has received consideration since it was proposed by Sanfelice in 1914.⁵ Stanley's work provides experimental support for this theory.

SULPHUR THERAPY

The utilization of sulphur for medicinal purposes was described as early as the time of Pliny,¹ who attributed therapeutic value to this element in a wide variety of ailments. Medical interest in sulphur has been stimulated by the preparation of this material in forms² whereby it may be introduced intramuscularly and intravenously. Much has been written concerning the wide therapeutic value of sulphur, but its use in widely different fields suggests that the theoretical basis of sulphur medication is largely empirical. As a result, the many beneficial results attending the administration of sulphur have been accompanied by a certain proportion of unfavorable prognoses. For example, the failure to observe aseptic precautions during intramuscular administration of preparations of sulphur in oil has frequently led to periostitis, in some instances the dangers of an oil embolism have been encountered. Notwithstanding these difficulties, injections of sulphur in oil have been widely employed within recent years in the treatment of a variety of conditions.

The Danish clinician Schroeder³ first suggested the use of a preparation of sulphur in oil in the treatment of dementia paralytica and certain other nervous and mental disorders. The primary object of the therapy is to produce a series of pyrexial bouts, any favorable results that ensue are usually attributed to the beneficial effects of the fever. The therapeutic value appears primarily to be a general reaction associated with the rise of temperature, although some claim a specific sulphur effect. The results of Schroeder have been extensively studied by English investigators. In contrast to the rapid and dramatic results which he described, subsequent experimentation has produced comparative failure.⁴ Recently, a study⁵ of a series of twenty-three cases of dementia praecox treated with a preparation of sulphur in oil gave slight indications of improvement, although it was difficult to distinguish between therapeutic improvement and spontaneous amelioration. One of the most characteristic effects of the sulphur injections appears to be a leukocytosis. This phenomenon has been studied in some detail both in man and in rabbits by Power⁶ and has been demonstrated to be due to an increase in polymorphonuclear cells. Furthermore, the leukocytes that appear in the circulation under these experimental conditions have been shown to exhibit, under *in vitro* conditions, a considerable degree of phagocytic activity.

Probably the most beneficial results of sulphur therapy have been claimed in dermatology. This is particularly true with the advent of new preparations. Miller⁷ has recently presented an interesting report of the uses that have been suggested for colloidal sulphur in dermatology, together with personal observations made in a wide variety of dermatologic conditions. Interesting comparisons have been made between the therapeutic value of colloidal sulphur and that of other forms of sulphur therapy. The application of this element in colloidal form was of no value for cutaneous conditions that in the past have not responded to other types of sulphur treatment. However, colloidal sulphur seemed to produce improvement in many instances in seborrhea, seborrheic dermatitis, acne rosacea, acne vulgaris and dermatomycosis. It also proved to be of value when applied as wet dressings in cases of subacute eczema and dermatomycosis. Certain types of fungous infections, for example ringworm of the feet, responded well to colloidal sulphur therapy. The latter treatment was, however, of little value in scabies, psoriasis or instances of pyogenic infections.

These results, together with cases reported by other investigators, may stimulate the use of sulphur as a therapeutic agent in dermatology. Sulphur in the colloidal form should be employed in much lower con-

centrations than those used for other forms of sulphur. It is generally advisable to use the material in less than a 5 per cent solution, and it requires considerable experience to determine the exact strength needed and the most suitable base or dispersion medium for the preparation. All preparations should be clear, free from an odor of hydrogen sulphide, of a p_H of approximately 5.0, and correctly standardized as to sulphur content.

Current Comment

SIGNIFICANCE OF CALCIUM ION CONCENTRATIONS IN THE BLOOD

At least part of the diffusible calcium in the blood serum is in the form of free ionic calcium. There is reason to believe that this form is of primary physiologic importance. Two schools of thought, both supported by experimental evidence, have developed with regard to the state of this diffusible calcium. One has held that all or nearly all the calcium not bound to protein is ionized. The other believes that, of each 5 mg of calcium not bound to protein, not more than 2 mg can be in the ionized state. In order to account for the remaining 3 mg a diffusible form of calcium, bound to some citrate-like substance, as yet unidentified, has been postulated. In view of the uncertainty as to the conditions present in the fluids of the normal body, it is not surprising that interpretation of abnormal observations has been a source of great difficulty. To the clinician this has meant (1) that a normal figure for the total calcium of the serum might possibly conceal an abnormal distribution between the various forms, and (2) that no sound basis has existed for clinical interpretation of abnormal fluctuations in the total calcium level. The key to these difficulties lies in the possibility of making direct observations of ionic calcium concentrations. McLean and Hastings¹ have reported a method designed to resolve this problem. They used the isolated heart of the frog, already known to be extremely sensitive to changes in the calcium content of its nutrient fluid. It had been previously² shown that this sensitivity could be reduced to quantitative terms. The ionic calcium concentration in normal human fluids was found to be in the neighborhood of 5 mg per hundred cubic centimeters of fluid, and this held true whether cerebrospinal fluid, containing a total of 5 mg of calcium per hundred cubic centimeters, or a serum containing twice this amount was examined. It thus appears that all or nearly all the calcium in protein-free fluids is present in ionized form and that in protein-containing fluids, such as serum, plasma, pleural fluid and ascitic fluid, ionic calcium and calcium bound to protein are together sufficient to account for all or nearly all the total calcium. There thus seems no further reason to propose quantitatively significant amounts of a third form of calcium in the fluids of the

normal human body. It can scarcely be doubted, however, that a small but insignificant amount of bound but diffusible calcium, corresponding to the small amounts of citrate present in human fluids, does exist in these fluids. The calcium-protein relationship was next investigated, and this study led to the discovery that the ionization of calcium in protein-containing fluids is determined by a chemical equilibrium between calcium and protein. With the demonstration that the distribution of calcium between ionic calcium and calcium bound to protein depends on the total protein present, it becomes possible to calculate ionic calcium concentrations from values for total calcium and total protein. The first conclusion is that values for ionic calcium concentrations as calculated from total calcium and total protein are in substantial agreement with the values obtained from direct observation by the frog heart method. The usual and simple method for calculating ionic calcium concentrations from total calcium and total protein thus appears entirely adequate for ordinary clinical use.

NEW REGULATIONS CONCERNING INJURED EMPLOYEES OF WORKS PROGRESS ADMINISTRATION

The Emergency Relief Appropriation Act of 1935 provides that the provisions of the Federal Employees' Compensation Act are extended, as far as applicable, to employees of the Federal Civil Works Administration for disability or death resulting from traumatic injury sustained while in the performance of duty. Traumatic injury includes "only injury by accident causing damage or harm to the physical structure of the body and shall not include a disease in any form except as it shall naturally result from the injury."

The administration of the Federal Employees' Compensation Act is vested in the United States Employees Compensation Commission, Washington, D. C., the commission being authorized to make necessary rules and regulations for the carrying out of the purposes of the act. Pursuant to this authority, the commission, July 15, 1935, promulgated Rules and Regulations No. 1, Governing Compensation and Medical Expense for Works Progress Administration.

SUMMARY OF RULES AND REGULATIONS No 1

The term "employee" includes only persons receiving security payments or wages from funds made available by the Emergency Relief Appropriation Act of 1935 for services rendered as employees of the United States. The term "physician" includes only graduates of a recognized medical school with a degree of M.D. who are licensed to practice medicine in the state in which they reside. The term "state compensation officer" as used in the regulations refers to the person on the staff of each State Works Progress Administrator who is charged with the duty of supervising the handling of compensation claims.

MEDICAL TREATMENT

Employees of the Works Progress Administration who suffer a traumatic injury while in the performance of duty, whether or not disability arises are entitled to necessary medical and hospital care. Treatment will not be authorized for illness or disease in any form except as it may naturally arise from a traumatic injury by accident causing harm or damage to the physical structure of the body. No provision is made for medical examinations to determine employees' physical qualifications for work.

Where practical medical treatment is to be furnished by federal medical establishments but these facilities may not be

utilized to the exclusion or disadvantage of any other beneficiary for whom they have been specifically provided. Where federal medical facilities are not available, or where such facilities are inadequate to furnish the necessary services, the state compensation officer or his local representatives are authorized to make arrangements for medical care by reputable private physicians.

Medical fees are to be paid at rates not in excess of the minimum charges prevailing in the community for similar services. The regulations provide that the state compensation officer or his local representatives should contact the local medical societies to enlist their cooperation in selecting physicians in the locality who are especially well qualified to render services in industrial accident cases and who desire to render such service to employees of the Works Progress Administration, under the regulations of the commission. The fact that a physician, otherwise qualified, is not a member of a medical society is not to be considered in a way discriminatory to him. Compensation cases are to be distributed among physicians in as equitable a manner as possible.

A physician authorized to treat an injured employee may select the institution in which a patient is to be hospitalized, provided such institution agrees to the approved schedule of rates. The commission has agreed with representatives of the national hospital associations on basic rates with general hospitals for services to Works Progress Administration employees. The commission reserves the right to have its medical representatives examine patients and their records at the hospital and to cause a patient's removal for sufficient reason.

AUTHORITY FOR TREATMENT

Where there is no doubt concerning the right of an employee to receive medical care, special form CA-16, or a letter containing the information required by that form, must be issued by the person in charge of a project or the compensation representative, in sending an injured employee to a physician or hospital for treatment. The request is made in duplicate and the original is left with the physician or hospital.

If there is doubt whether or not an employee is entitled to medical and hospital care, the person in charge of the project, or the local compensation representative, should send the employee for an examination, using special form CA-17. If the examination discloses that the employee is not entitled to treatment, the local compensation representative or other person who issued form CA-17 should immediately notify the physician or hospital that no treatment should be rendered for the account of the commission. If the local compensation representative is in doubt concerning the matter, he is to refer all details and circumstances to the state officer for advice. If the state officer entertains doubt, he is to refer the facts to the commission, at Washington, D. C., for decision. Form CA-17 authorizes necessary emergency treatment.

Form CA-16, or form CA-17, is the physician's authority for rendering services for the account of the commission, and bills cannot be paid in the absence of such authority. The regulations provide that authorization for treatment of an injured employee should not be issued to more than one physician, if a second physician is necessary, the attending physician has full authority to procure such assistance as he may deem necessary. If, however, a change of physicians becomes advisable, authority for treatment is to be issued to the physician to whom the case is transferred.

Authorization for treatment, the regulations provide, should be issued on the date of the injury or on the date the employee applies for treatment and should be sent to the physician at the time the employee is referred for treatment. Emergency cases may be referred before the issuance of form CA-16, provided the form is issued within forty-eight hours thereafter. When it is not practical to observe this requirement the delay in issuing authorization must be explained—otherwise payment for medical services may be refused. All authority for treatment or hospitalization should be signed personally by the issuing officer. The name of the issuing officer typed on the form is not to be considered valid authority.

Attending physicians may engage special nursing service when such care is absolutely essential without written authorization by the compensation officer. The commission's allowance for

hospitalization covers all general nursing service. The necessity for special nursing must be shown in each case. Vouchers submitted by nurses must contain a certification that they are not employed on a salary basis in the hospital in which the service was rendered, and these vouchers must be approved by the attending physician.

HERNIAS

Special provisions are embodied in the regulations with respect to hernias. Form CA-17 should be used in all hernia cases. In general, no hernia operation is to be authorized by the state compensation officer, but such cases must be reported to the commission at Washington for authorization to proceed with the operation. In an emergency, however, "due to strangulation or incarceration," when it is clear that the complication is due to injury on a Works Progress Administration project, an emergency operation may be authorized locally. The provisions of the commission's general regulations promulgated under the Federal Employees' Compensation Act, relating specifically to hernias, are made applicable to cases of hernias developing in connection with the Works Progress Administration activities.

PREPARATION OF VOUCHERS FOR MEDICAL AND HOSPITAL SERVICE

Bills for medical and hospital services are to be submitted on form S-69 and supported by proper written authority authorizing such service, either special form CA-16 or CA-17 as the case may be, unless such authorization has previously been forwarded to the commission. A separate voucher must be submitted by each payee for services to each indigent employee.

Vouchers should be verified by the signature of the injured employee. Vouchers from physicians and hospitals on form S-69 should be submitted when the employee is discharged from treatment except when hospitalization or treatment extends more than thirty days, in which case the vouchers should be submitted at the end of each thirty-day period with a complete report from the attending physician showing the condition of the employee, the diagnosis and prognosis, and recommendations with reference to any future medical care.

VOUCHERS SUBMITTED BY PHYSICIANS

The following specific instructions should be followed by physicians, in submitting voucher form S-69: (a) All charges must be itemized to show specific dates on which treatments were rendered, the charge for each treatment and a concise description of the injury for which treatment was rendered. (b) X-ray charges should be itemized so as to show the dates on which made, number of views, parts of the body roentgenographed, and the charge for each service. (c) Joint accounts will not be authorized for payment. If the service of an assistant or consultant is required, the assistant or consultant must submit a separate voucher. (d) Physicians and hospitals must not submit a combined account. (e) Vouchers from physicians shall include a separate charge for drugs and must show whether such drugs were supplied from personal stock. If not, a receipted bill supporting the charge must accompany the voucher. All charges for drugs must be itemized.

VOUCHERS FOR HOSPITAL SERVICE

The following specific instructions must be followed in submitting voucher form S-69 for authorized hospital service: (a) Payment will be made for the day of admission but not for the day of discharge from the hospital, and vouchers should be submitted accordingly. (b) The per diem rate for hospitalization includes all drugs, dressings and laboratory work. (c) Payment for special drugs and supplies authorized by the attending physician will be approved. Whenever extra charges for special drugs or surgical supplies are made, the kind of drugs must be shown on the voucher and, if they are not supplied by the hospital, the amount claimed must be supported by a properly receipted bill. If not supplied from stock or supported by a receipted bill, the cost of the article should not be included in the hospital voucher and the druggist or firm supplying the articles should be instructed to submit a voucher. (c) All x-ray charges should be itemized as described

in the preceding paragraph. (d) Hospitals and physicians must not submit a voucher combining the services of the two. When the physician is owner or part owner of the hospital, and accounts are submitted in the physician's name or in the name of the hospital, a separate voucher must be prepared for each class of service.

IN GENERAL

The regulations further provide, in detail, for the payment of necessary expenses incurred in the transportation of injured employees for the purpose of obtaining medical treatment, for the filing of reports of injuries, and for the payment of compensation to injured employees or their surviving dependents.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ARIZONA

Appointments to State Medical Board—Members of the Arizona State Board of Medical Examiners, recently appointed by the governor, and their terms of office are: Dr. John H. Patterson, Phoenix, secretary, six years; Dr. William G. Schultz, Tucson, five years; Dr. Ira E. Huffman, Tucson, four years; Dr. John E. Bacon, Miami, three years; and Charles C. Bradbury, D.O., Phoenix, two years. Dr. Bacon is a new appointee to the board.

CALIFORNIA

Society News—A recent meeting of the Humboldt County Medical Society was addressed, among others, by Dr. Emmet Rixford, San Francisco, on "Surgery of the Gallbladder and Stomach."—At a meeting of the Lassen-Plumas County Medical Society in Westwood, May 3, it was voted to petition the state society to change the name to Lassen Plumas Modoc County Medical Society.—Speakers before the Orange County Medical Society, June 4, included Drs. Vernon P. Thompson on "Treatment of Fractures of the Long Bones of the Lower Extremities", Donald G. Tollefson, "Toxemias of Pregnancy", Charles E. Phillips "Surgical Relief of Ulcer of the Stomach", Pierre P. Viole, "Treatment of Sinusitis," and Edward Richmond Ware, "Coronary Thrombosis—Management and Treatment." All are from Los Angeles.—At a meeting of the San Bernardino County Medical Society in the Patton State Hospital, June 11, Drs. James J. Cecil, Patton, discussed "Syphilitic Diseases of the Brain and Spinal Cord" and Harry S. Blossom, Patton, "Dementia Praecox."—Medical economies was discussed before a meeting of the San Joaquin County Medical Society in Stockton, June 6, by Drs. Guillaume D. Delprat and Glenn F. Cushman, San Francisco.—The Tulare County Medical Society was addressed, June 2, by Dr. Edward C. Bull, San Francisco, on "Fractures About the Ankle."

CONNECTICUT

Personal—Dr. Cornelius S. Conklin, Bridgeport, has been named president of the Bridgeport Medical Society, to fill the unexpired term of the late Dr. Daniel J. McCarthy.—Dr. Grover F. Powers, professor of pediatrics, Yale University School of Medicine, received the honorary degree of doctor of science from Purdue University, Lafayette, Ind., recently.—The University of Leeds, England, conferred the honorary degree of doctor of science on Dr. Harvey Cushing, New Haven, July 1.

DISTRICT OF COLUMBIA

Changes on the Faculty at Georgetown.—Announcement is made of the following promotions and appointments on the faculty of the Georgetown University School of Medicine for the next academic year:

Dr. Vincent J. Dardinski, professor of anatomy and director of the department, has been associate professor of pathology and parasitology.
Dr. Reginald A. Cutting, professor of physiology and director of the department.
Dr. John A. Simpson, assistant professor in the department of pathology and parasitology.
Dr. Philip L. Martinez, assistant professor in the department of anatomy.
Dr. George J. Brimley, professor of pathology and parasitology.
Dr. Harold V. Connerty, assistant professor of pathology and parasitology.

GEORGIA

Personal—Dr Josephus J P Bowdoin, Atlanta, has been given a life membership in the Seventh District of the Georgia Congress of Parents and Teachers "in appreciation of his service to the children of the state"—Dr Samuel P Hall Jr, formerly of Chickamauga, has been named health commissioner of Walker County to succeed Dr Rufus F Payne, who resigned to accept a position with the CCC Camp at Fort Oglethorpe—Dr Lysander P Holmes has been appointed superintendent of the University Hospital, Augusta, succeeding Dr John H Snoke, resigned

ILLINOIS

Society News—Dr Rolland L Green, Peoria, president-elect of the Illinois State Medical Society was guest of honor at the annual outing of the Peoria City Medical Society, June 27, at Luthy's Alps—Dr Frederick H Falls, Chicago discussed "Early Diagnosis of Cancer of the Uterus" before the Coles-Cumberland Counties Medical Society, July 12

Personal—Thomas C Grubb Ph D, has been appointed a member of the professional staff of the Illinois State Department of Health and will conduct research in the control and prevention of disease. Dr Grubb is a graduate of the University of Chicago and in 1934 shared the Ricketts prize at the university for meritorious work relating to the diphtheria bacillus—Dr Grover C Brown, Sainte Marie, has been appointed managing officer of the Jacksonville State Hospital

Chicago

Personal—Dr Margaret W Gerard, assistant clinical professor of psychiatry, Division of Biological Sciences, University of Chicago, has been promoted to be associate professor under the psychiatric program recently instituted at the university—The honorary degree of doctor of laws was conferred on Dr Arthur Hale Curtis, professor of obstetrics and gynecology, Northwestern University Medical School by the University of Wisconsin June 24

IOWA

Society News—A county tuberculosis association will be established in Cerro Gordo County, in accordance with a plan adopted by the county medical society at its meeting, June 21 in Mason City Dr Nathaniel G Alcock, Iowa City, discussed transurethral prostatectomy before the society at this meeting—Speakers before the Austin Flint-Cedar Valley Medical Society in Mason City, July 9, included Drs Louis A Buie, Rochester, on proctology Lawrence E Kelley Des Moines, analgesia in labor, and Henry D Holman Mason City therapeutic hints for the treatment of angina pectoris and coronary occlusion

Baker Charged with Practicing Medicine—It was reported July 24, that Justice J C Coster Muscatine, had ordered Norman G Baker held to the September grand jury The charge was that of conspiring to practice medicine without a license The judge overruled a motion by Baker's attorney to dismiss the charge against him. Baker was arrested one hour after his return to Muscatine from Nuevo Laredo, Mexico where he operates a 'cancer cure hospital and radio station He posted a bond of \$1,000 Baker's permit to operate a station in Muscatine was canceled in 1931 because of his pernicious broadcasting Feb 14, 1935 Baker applied for a permit to open a new broadcasting station in Muscatine his application was denied (THE JOURNAL, March 16, p 629)

KANSAS

Department of Medical Research.—The establishment of a department of medical research at Bell Memorial Hospital, Kansas City as a part of the work of the University of Kansas School of Medicine with Dr Ralph H Major professor of medicine, as director, has been announced Clarence J Weber Ph D instructor in medicine has been named associate in medical research

New County Societies—The Chautauqua County Medical Society was organized at a meeting in Sedan June 28 and the following officers were elected Dr Edward A Varrs Sedan president Dr Estella M Edwards Cedar Vale vice president and Dr Ralph S Casford Sedan secretary treasurer Dr Benjamin Brunner Wamego was chosen president of the Pottawatomie County Medical Society at its organization meeting recently in Westmoreland

State Medical Election—Dr Howard L Snyder Winfield, was chosen president of the Kansas Medical Society at the recent annual meeting to take office January 1 succeeding Dr John F Hassig Kansas City Other officers of the society are Drs Lewis D Johnson Chanute, vice president Harry L

Chambers Lawrence, secretary and George M Gray, Kansas City treasurer Mr Clarence G Munns, Topeka, is executive secretary The next annual session will be held in Topeka, May 6-8 1936 The society agreed to establish a permanent committee on maternal welfare to be composed of five members, three of whom shall be obstetricians, one a surgeon and one an internist

MARYLAND

Personal—Dr George O Sharrett, Cumberland was recently elected to fill the unexpired term of the late Dr Henry M Fitzhugh, Westminster, as a member of the Board of Medical Examiners of Maryland

New Milk Regulations—The state department of health has adopted new regulations governing the control of milk shipped, handled and consumed in Maryland Pasteurization apparatus must be approved by the state department, according to the new requirements and must have proper temperature control the milk must be heated to a temperature of not less than 143.5 F continuously for not less than thirty minutes and then properly cooled. Grades are defined as A, B and C raw milk and A and B pasteurized Grading is not compulsory, but milk offered for sale as graded must conform to the requirements The amended regulations do not apply to cities of more than 100,000 of population which have an organized department of health and which maintain milk supervision under state law or city ordinances, incorporated cities or towns are authorized to adopt and enforce milk regulations that are not inconsistent with those of the state board of health and to provide for the grading of milk, counties may use the same privilege.

MASSACHUSETTS

State Board Election—At the annual meeting of the Massachusetts Board of Registration in Medicine, July 11, Dr Charles P Sylvester, Boston, was reelected chairman and Dr Stephen Rushmore, Boston, reelected secretary

Personal—Dr Ernest E Tyzzer, George Fabyan professor of comparative pathology, Harvard University Medical School, Boston, received the honorary degree of doctor of science at the annual commencement of Brown University, Providence

Psychiatric Awards—Dr Calvert Stein of the Monson State Hospital received the first prize of the New England Society of Psychiatry at its recent annual meeting, for a paper on 'Studies in Endocrine Therapy in Epilepsy' Dr Minna E L Emch of the Worcester State Hospital was given second prize for her paper on 'A Reorientation for State Hospital Psychiatry' These awards are presented annually for the best papers embodying research in psychiatry completed during the year Dr Horace G Ripley, superintendent, Brattleboro Retreat, Brattleboro Vt, was chosen president Dr Eugene A Stanley, superintendent, Vermont State Hospital for Insane, Waterbury, vice president and Dr Harlan L Paine, superintendent, Grafton State Hospital, North Grafton, secretary-treasurer Dr William A Horsley Gantt, director of the conditioned reflex laboratory, Johns Hopkins University School of Medicine, Baltimore, spoke on the experimental approach to psychiatry

MINNESOTA

Personal—Northwestern University, Evanston, Ill conferred the honorary degree of doctor of science on Dr Henry S Plummer, Rochester, at its annual commencement—Dr Baldwin Borreson has been appointed to succeed Dr Bethune C Bernard as superintendent of Oakland Park Sanatorium, Thief River Falls

Northern Minnesota Medical Meeting—The annual meeting of the Northern Minnesota Medical Association will be held in Duluth, August 12, with the following physicians, among others, on the program

Melvin S Henderson Rochester Fractures of Neck of Femur
John H Moore Grand Forks N D Pelvic Inflammatory Disease
Edward N Peterson Eveleth Lung Abscess
Richard M Johnson Minneapolis New Concepts of Calcium Therapy
Arthur U Desjardins Rochester Radiotherapy for Inflammatory and Malignant Conditions
Owen W Parker Ely Fractures of the Ankle
Clarence Jacobson Chisholm Management of Diabetes Mellitus in General Surgery
James J Swendsen St Paul Sterility Its Etiology and Treatment
Edgar T Herrmann St Paul Treatment of Pneumonia by Artificial Pneumothorax
Herbert A Carlson Minneapolis Treatment of Acute Empyema
Gordon B New Rochester Management of Malignant Disease of the Mouth and Adjacent Structures
Rosco G Leland Chicago Medical Economics

A steamer trip along the north shore of Lake Superior is planned

Appointments of Drs Scammon and Diehl—Richard E. Scammon, Ph D, since 1931 dean of medical sciences, University of Minnesota School of Medicine, has been appointed Distinguished Service Professor of the graduate faculty of the University of Minnesota, a new position. He will be free to devote a portion of his time to research and to teach, if he wishes, in any school of the university that wants his services. Dr Scammon, who is 52 years of age, received his degree of doctor of philosophy from Harvard in 1909. He was assistant professor of anatomy at the University of Kansas from 1910 to 1911, then went to the University of Minnesota as assistant professor. He was professor from 1914 to 1930, when he resigned to become professor of anatomy and dean of the Division of Biological Sciences, University of Chicago. In 1931 he returned to Minnesota as dean of medical sciences. He was president of the Minnesota Board of Examiners in Basic Sciences from 1927 to 1930. Dr Harold S. Diehl, professor and head of the department of preventive medicine and public health since 1922, will succeed Dr Scammon as dean of medical sciences. Dr Diehl is 44 years of age and graduated in medicine at Minnesota in 1918. In addition to his professorship he has been director of the student health service.

MONTANA

State Medical Meeting and Election—Dr John A. Evert, Glendive, was chosen president-elect of the Medical Association of Montana at its fifty-seventh annual meeting, in Helena, July 2-3. Dr Louis H. Flugman, Helena, was installed as president. Dr Harry J. McGregor, Great Falls, was named vice president, and Dr Elmer G. Balsam, Billings, was reelected secretary. The next annual meeting will be held in Billings, July 8-9, 1936. Speakers on the scientific program included

Dr Jay Arthur Myers, Minneapolis, Modern Aspects of the Diagnosis and Treatment of Tuberculosis
Dr Rosco G. Leland, Chicago, Medical Economics
Dr Frank E. Burch, St. Paul, Ophthalmology
Dr Francis L. McPhail, Great Falls, Treatment of Eclampsia
Dr Lloyd T. Sussex, Havre, Chronic Infections of the Urinary Tract
Dr John R. Vasko, Great Falls, Low Back Pain
Dr Herbert H. James, Butte, Treatment of Uterine Myoma and Myopathic Hemorrhage with Radium

On Tuesday, July 2, the association held a joint meeting with the Western Branch of the American Public Health Association, which was holding its sixth annual session. Speakers at this meeting included

John F. Kassel, Ph D, Los Angeles, Epidemiologic and Laboratory Studies During the 1934-1935 Poliomyelitis Epidemic in Los Angeles
Dr Enoch M. Porter, Great Falls, After Care of Infantile Paralysis
Dr Roger A. Nolan, San Diego, Infectious Mononucleosis
Dr Henry E. Young, Victoria, B. C., Canada, Medical Economics in Canada

That evening both groups attended a banquet at the Consistory Temple with Dr Balsam as toastmaster. Drs Walter H. Brown, Palo Alto, Calif., and Charles E. K. Vidal, Deer Lodge, presidents of the Western Branch and the Montana association, respectively, were the speakers. A joint stag dinner was held, July 1, William Shea, Great Falls, spoke on "These Doctors," and Dr Thomas F. Walker, Great Falls, "These Inspectors."

NEW YORK

Personal—Dr Howard H. Volan, Syracuse, has been appointed epidemiologist in the Syracuse department of health to succeed Dr Gregory D. Mahar, who was recently made health commissioner.—Dr Arthur R. Bowles, Mount Kisco, has been appointed assistant director of Grasslands Hospitals, Valhalla, to succeed Dr William B. Talbot, who has been made superintendent of the New York Post-Graduate Hospital.

Annual Meeting at Chautauqua—The Chautauqua County Medical Society sponsored its annual interstate meeting at Chautauqua, July 24, with physicians from New York, Pennsylvania and Ohio as guests. Speakers were Drs Donald R. McKay and Raymond S. Rosedale, Buffalo, on "Primary Carcinoma of the Lung," Walter M. Simpson, Dayton, Ohio, "Undulant Fever," and M. Herbert Barker, Chicago, "Treatment of Pneumonia." Dr Joseph Colt Bloodgood, Baltimore, delivered a public address on cancer at an afternoon meeting, which was followed by the annual golf tournament.

Society News—The Binghamton Academy of Medicine, the Broome County Medical Society and the Endicott Johnson Medical Society were guests of the Binghamton Psychiatric Society, May 27, at a meeting at the Binghamton State Hospital, at which Dr Israel S. Wechsler, New York, discussed "Traumatic Neurosis."—The May meeting of the Seneca County Medical Society was held at Seneca Falls, with Drs John M. Swan, Rochester, and Jacob J. Levy, Syracuse, as speakers, on cancer. Dr John F. Crosby, Seneca Falls, was guest of honor at a dinner preceding the meeting, in compli-

ment to his fifty-two years as a physician.—Dr Chalmers J. Longstreet, Binghamton, was elected president of the New York State Sanitary Officers' Association at the annual meeting in Saratoga Springs, June 26, and Dr Guy H. Turrell, Smithtown Branch, L. I., secretary.—The Lake Keuka Medical Society canceled its annual meeting, which was to have been held July 11. Lake Keuka is in the flood area.

New York City

Personal—Dr Stephen H. Ackerman has been appointed medical superintendent of Coney Island Hospital to succeed Dr Marcus D. Kogel, who will be in charge of the new Queens General Hospital, the department of hospitals announced recently.—Dr Oswald T. Avery of the Rockefeller Institute for Medical Research received the honorary degree of doctor of laws at the annual convocation of McGill University, May 30.—Drs Maurice C. O'Shea, Lawrence M. Shapiro and Emeline P. Hayward have been provisionally appointed to the medical staff of the board of education. These positions have been vacant for several years.

Appointments at Rockefeller Institute—Dr Alphonse R. Dochez has been elected a member of the board of scientific directors of the Rockefeller Institute for Medical Research. Drs Lawrence Edgar Hummel and Robert J. Parsons have been appointed assistants on the staff of the institute, Dr William Halsey Barker and Mr Rollin D. Hotchkiss, fellows. Promotions include the following:

Assistant to associate: Drs Joseph W. Beard, Harry S. N. Green, Kenneth C. Smithburn and Wendell M. Stanley, Ph D.
Fellow to assistant: George L. Graham, Sc D, George I. Lavin, Ph D, Charles V. Seastone, Jr., William Trager, Ph D, and Arnold J. Ulstrup, Ph D. Jonathan Biscoe and Joseph S. Fruton.

Neurological Institute Reorganized—Dr Frederick Tilney, professor of neurology and neuro-anatomy at the College of Physicians and Surgeons of Columbia University, has been appointed to the new position of medical director of the Neurological Institute in a reorganization effected July 9. Dr Dudley D. Roberts was named vice president and chairman of the executive council, and twenty-five new trustees were added to the previous twenty-five. A new department is to be organized in association with the College of Physicians and Surgeons to develop research in physiology of the nervous system and it is also planned to enlarge the department of child neurology recently organized through the Friedsam Foundation under the direction of Dr Bernard Sachs. Laboratory facilities will be extended to several additional floors of the institute, it was announced. In addition, ten new committees have been designated to deal with scientific matters, finance, hospital management, professional staff, nurses, outpatient department, education, buildings and grounds, publicity and community relations and law. The Neurological Institute was founded in 1909 and became a part of the Columbia University-Presbyterian Hospital Medical Center in 1929.

NORTH CAROLINA

Society News—A symposium on acute poliomyelitis was presented before the Buncombe County Medical Society, Asheville, July 1, by Drs Lewis W. Ehasz, Henry H. Harrison and George W. Kutscher, Jr.—Dr Charles M. Byrnes, Baltimore, addressed the Guilford County Medical Society, High Point, June 6, on "Functional Neuroses and Their Treatment."—A symposium on accidental injuries made up the program of the Catawba Valley Medical Society, Lincolnton, July 9, presented by Drs Verne H. Blackwelder, Lenoir, Jefferson Byrns Helms and John S. McKee, Jr., Morganton.

PENNSYLVANIA

Personal—Dr Louis A. Wesner, Johnstown, has been appointed medical director of the State Sanatorium for Tuberculosis at Cresson, succeeding Dr Thomas H. A. Sutes.—Dr and Mrs Anson J. Singer, East Stroudsburg, recently celebrated their golden wedding anniversary.—Dr George A. Clark Wilkes-Barre, completed fifty years in the practice of medicine, May 18.—Dr Harry W. Howland, Gaines, has been appointed medical director of Tioga County, succeeding Dr Charles W. Sheldon, Wellsboro.

Philadelphia

Dr Long Appointed Director of Phipps Institute—Dr Esmond R. Long, director of the laboratory of the Henry Phipps Institute of the University of Pennsylvania, has been made director. Dr Charles J. Hatfield, former director, will be associate director and chairman of the board of directors in charge of the institute. Dr Henry R. M. Landis will have the title of associate director in charge of the clinical and sociological departments.

SOUTH CAROLINA

Lectures on Obstetrics—Dr James R. McCord, Atlanta gave a series of lectures on obstetrics for practicing physicians in Columbia, July 8-12. The lectures were sponsored by the Columbia Medical Society and the South Carolina Medical Association and were attended by physicians from nine counties.

Personal—Friends of Dr Joseph H. Saye, Sharon, held a community celebration in honor of his fiftieth anniversary of medical practice in the town, June 1.—Dr William A. Carrigan, Society Hill, has been appointed health officer of Darlington County.—Dr Sedgwick Simons, Georgetown, has been assigned as health officer of Beaufort County.

TENNESSEE

Society News—Dr Dean DeWitt Lewis, Baltimore, addressed the Chattanooga Surgeons' Club, July 9, on "Nerve Injuries." At a banquet given in his honor, July 10, at the Chattanooga Golf and Country Club, Dr Lewis spoke on medical economics and later addressed the Chattanooga and Hamilton County Medical Society on "Differential Diagnoses in Abdominal Conditions."—Four Memphis physicians addressed the July meeting of the Benton-Carroll-Henry-Weakley Counties Medical Society at Huntingdon, July 9, as follows: Drs Joseph A. Crisler "Recurrence of Carcinoma After Ten Years", Peter Whitman Rowland Jr., "Diagnosis of Angina Pectoris", John C. Ayres, "Common Errors in Obstetrics", and Frank T. Mitchell "Rheumatic Fever."—Drs Charles F. Webb, Jackson, and John L. McGehee, Memphis among others, addressed the medical society of Hardin, Lawrence, Lewis, Perry and Wayne counties at Shiloh National Park, June 25, on acute conditions in the abdomen and appendicitis in pregnancy, respectively.—Dr James G. Ehlen, Knoxville addressed the Knox County Medical Society, June 18, on "Treatment of Empyema in Children."

TEXAS

Hospital News—The University of Texas and the Sealy and Smith Foundation have appropriated \$200,000 for the erection of a hospital for Negroes as a unit of the John Sealy Hospital, Galveston, according to *Modern Hospital*.

University News—Richard E. Scammon, Ph.D., dean of medical sciences, University of Minnesota, Minneapolis, delivered the commencement addresses at Baylor University College of Medicine, College of Dentistry and College of Nursing, Dallas, May 27, and at the University of Texas School of Medicine, Galveston, May 31. There were eighty-three graduates at the state university and seventy-nine at Baylor.

Personal—Hubert S. Jackson, D.D.S., San Antonio, and Dr William P. Harrison, Teague, have been appointed to the state board of health.—Dr Arthur C. Scott Sr., Temple received the honorary degree of doctor of laws from Trinity University, Waxahatchie, June 3.—Dr Thomas N. Goodson, San Antonio, has been appointed health officer of Bexar County and Dr Lawton C. Biggers, Bonham, of Fannin County.—Dr William B. Carrell, Dallas, has been elected a member of the International Orthopedic Association; it is reported.

WASHINGTON

Personal—Dr Hinton D. Jonez, Tacoma, was recently appointed health officer of Pierce County to succeed Dr James H. Egan.—Dr Arthur M. Sonneland, Bellingham, has been appointed health officer of Whatcom County, succeeding Dr Johan C. Wuk.

Society News—Dr William A. Buice, director of laboratories at the Eastern State Hospital, Medical Lake, was elected president of the Washington State Public Health Association at its first annual meeting held recently in Wenatchee.—Drs Frank H. Wanamaker and Charles B. Ward, Seattle, addressed the Okanogan County Medical Society at Omak, June 12, on cancer of the lower jaw and cancer of the face and neck, respectively.

WEST VIRGINIA

Personal—Dr Guy Hinsdale White, Sulphur Springs, sailed June 1 to attend the meeting of the International Society of Medical Hydrology in Brussels, Belgium.—Dr Edward R. Davies, Kingwood, has resigned as health officer of Preston County to take a similar position in Baltimore, it is reported. Dr Davies' successor is Dr Charles Y. Moser, Terra Alta.

Society News—Drs. William S. Lovc Jr. and Charles Reid Edwards, Baltimore, addressed a joint meeting of the Monongalia, Marion and Harrison county medical societies, Morgantown, June 4, on "Differential Diagnosis and Signifi-

cance of Heart Murmurs" and "Thrombosis and Embolism," respectively. The guests conducted clinics during the day at the Monongalia County Hospital.—Drs Walter E. Vest and Fred A. Brown, Huntington, addressed the Logan County Medical Society, Logan, May 15, on "Methods of Gastro-Intestinal Diagnosis" and "Indications for Use of Digitalis," respectively.—Dr Joseph H. Barach, Pittsburgh, addressed the Tyler-Wetzel Counties Medical Society, in June, on "Changing Views on Hypertension."

HAWAII

Graduate Lectures—The Honolulu County Medical Society inaugurated a series of graduate lectures June 27, when Dr William Darrach, dean emeritus and professor of clinical surgery, Columbia University College of Physicians and Surgeons, New York, spoke on "Treatment of Fractures." Dr George Dock, Pasadena, Calif., also spoke on appendicitis. Dr Hugh H. Young, professor of urology, Johns Hopkins University School of Medicine, Baltimore, gave a lecture July 8, entitled "The Prostate Gland—Its Past and Present Treatment." He also conducted a urologic seminar, July 10, at the Queen's Hospital.

GENERAL

Dr Gardner Receives Trudeau Medal—Dr Leroy U. Gardner, director of the Saranac Laboratory for Study of Tuberculosis, Saranac Lake, N. Y., received the Trudeau Medal of the National Tuberculosis Association at the annual meeting in Saranac Lake, June 24. The award was made for his work on the pathology of tuberculosis, notably that dealing with the relation between tuberculosis and silicosis. Dr Gardner, a graduate of Yale University School of Medicine, went to Saranac Lake as pathologist for the Trudeau Foundation in 1919. He became director of the laboratory in 1927.

Epidemic of Typhoid—About 100 cases of typhoid were reported to the health department of Minneapolis between May 25 and July 15, according to Minneapolis newspapers. The department has made intensive investigation of all cases but has not determined the source of the infection. Samples of city water have been repeatedly analyzed without conclusive results. Incidental pollution was discovered in samples taken July 1 and 2 and chlorine sterilization was immediately increased.—A woman typhoid carrier in Muncy, Pa., was recently fined \$50 for having prepared food for a dinner following which twenty persons became ill of typhoid and five died, according to a newspaper report, July 5.

Institute for Hospital Administrators—The American Hospital Association will conduct its annual institute for hospital administrators on the campus of the University of Chicago, September 11-25. The program will be devoted to lectures, conferences and seminars, and students who attended the 1934 institute may select in advance one or more of the special subjects which they wish to study this year. Opportunities will be arranged for them individually to pursue these subjects intensively and they will be excused from clinics not related to their special fields. Information may be obtained from the executive secretary of the American Hospital Association, 18 East Division Street, Chicago.

Medical Bills in Congress—*Bills Introduced* H. R. 8941, introduced by Representative Jenckes, Indiana, proposes 'to prevent the adulteration, misbranding, and false advertising of food drugs, and cosmetics, in the commerce affected, for the following purposes, namely, to safeguard the public health and to protect the purchasing public from injurious deception.' H. R. 8953, introduced by Representative McSwain, South Carolina, proposes to provide for the care and treatment of members of the National Guard, Organized Reserves, Reserve Officers' Training Corps and citizens military training camps who are injured or contract disease while engaged in military training.

Society News—Dr Roy R. Kracke, Emory University, Ga., was chosen president elect of the American Society of Clinical Pathologists at the annual meeting in Atlantic City, June 6-8. Dr Robert A. Kilduffe, Atlantic City, was elected vice president and Dr Foster M. Jolins, New Orleans, was installed as president.—Dr Zoe Allison Johnston, Pittsburgh, was chosen president-elect of the American Radium Society at the annual meeting in Atlantic City and Dr George W. Grier, Pittsburgh, was installed as president. Next year's meeting will be held in Kansas City at the time of the annual session of the American Medical Association.—The National Medical Association will hold its annual session in New Orleans August 11-17.

Outbreaks of Poliomyelitis—The Virginia state department of health reports that ninety-nine cases of poliomyelitis were reported to the department from June 1 to July 12. The outbreak has been confined principally to the south central

section of the state, with sporadic cases occurring in July in other sections. Cases have been reported from twenty-five counties, among them one death. More than 300 cases had been reported in North Carolina from May 1 to July 8, with twenty-four deaths. It was announced July 13 that the epidemic appeared to be waning, fewer cases having been reported to the state health department during the preceding week than in the week ended July 6, forty-eight cases were reported in the week ended July 20, compared with fifty-two July 13. Newspapers report twenty-six cases of poliomyelitis in Kern County, Calif., with four deaths since July 1.

Milk-Borne Epidemics in 1934—Twenty-one health departments in the United States and Canada reported forty-four milk-borne epidemics during 1934, all but one caused by the use of raw milk. According to data collected by the Conference of State and Provincial Health Authorities of North America, there were 1,382 cases of illness, with forty-seven deaths. The diseases involved in the epidemics were diphtheria, gastro enteritis, scarlet fever, septic sore throat, typhoid and undulant fever. Typhoid was responsible for 53 per cent of the epidemics and septic sore throat accounted for 22 per cent. These two diseases were responsible for 75 per cent of the epidemics, 70 per cent of the cases and 91 per cent of the deaths. Eighteen state health departments reported forty epidemics, with 1,324 cases and forty-four deaths, and Canadian officers reported four, with fifty-eight cases and three deaths. In those in the United States, carriers and cases in dairies were reported to have been the sources of contamination in 70 per cent, cows in 27 per cent. Seventy-four per cent of the forty-two communities in which the epidemics occurred were rural communities and small towns of less than 5,000 population, only one city with more than 50,000 population had a milk-borne epidemic during 1934. Forty-one health departments reported no epidemics during the year.

Bequests and Donations—The following bequests and donations have recently been announced:

Montefiore Hospital New York \$31,631 and Mount Sinai Hospital New York \$25,000 under the will of the late Isabella Kritzman.
St. Vincent's Hospital Bridgeport Conn. a share in the \$125,000 estate of the late Dr. Daniel J. McCarthy Bridgeport.
Children's Hospital St. Paul \$25,000 by the will of the late Leo Vogel Mankato Minn.
Lankenau Hospital and Hospital of the Protestant Episcopal Church Philadelphia \$5,000 each by the will of the late Henry Dittman.
Chestnut Hill Hospital Philadelphia \$10,000 from the estate of Mrs. Elizabeth Cuthbert Roberts Wyatt.
Jefferson Medical College Philadelphia \$5,000 by the will of the late Dr. Thomas McCrae.
Presbyterian Hospital Philadelphia \$5,000 by the will of Mrs. Florence F. Craig to be paid after the death of her husband.
St. Vincent's Hospital New York \$10,000 and Presbyterian Hospital New York \$7,500 by the will of Walter J. M. Donovan.
Montefiore Hospital for Chronic Diseases and Beth Israel Hospital \$6,000 each Lebanon Hospital \$2,500 by the will of Leo Lesser. All are in New York.
Hahnemann Medical College and Hospital Philadelphia, stock in a theater ticket printing company, valued at \$22,000 by the will of the late Bertha Galland.
Methodist Hospital Philadelphia \$2,000 and Aid Association of the Philadelphia County Medical Society \$1,000 by the will of the late Dr. Delno E. Kercher.
St. Luke's Hospital New Bedford, Mass. \$50,000 by the will of Miss Amelia Hickling Jones.
University of Wisconsin \$10,000 for the study of cancer by the will of the late Michael W. McArdle Chicago.
Presbyterian Hospital Chicago \$10,000 by the will of the late Mrs. Roxana Atwater Wentworth Bowen New York.

CANADA

Dr. Banting Honored—Sir Frederick Banting, professor of medical research, University of Toronto Faculty of Medicine, received the gold medal of the Society of Apothecaries of London, June 4, "for valuable services rendered to the science of therapeutics." He was also made a Fellow of the Royal Society and, June 20, delivered an address on the history of insulin at the British Postgraduate Medical School, Hammersmith.

Medal Awarded for Work in Anesthesia—Dr. Wesley Bourne, lecturer in anesthesia, McGill University Faculty of Medicine, Montreal, has received the first Hickman Medal of the Royal Society of Medicine of England. This award was founded in 1931, to be given every three years for original work of outstanding merit in anesthesia or directly related subjects. Hickman was a pioneer in the use of nitrous oxide as an anesthetic. He died in 1829.

Personal—Dr. Jonathan C. Meakins, Montreal, president of the Canadian Medical Association and past president of the American College of Physicians, has been made a fellow of the Royal College of Physicians of London.—Dr. James B. Collip, professor and head of the department of biochemistry, McGill University Faculty of Medicine, Montreal, received the honorary degree of doctor of laws, honoris causa, from the University of Manitoba.

Bill to Check the Advertisement of Nostrums

The misleading, not to say fraudulent, claims made for nostrums, otherwise termed "patent medicines," in the advertisements of newspapers have long been a scandal. Some years ago the British Medical Association tried to deal with the evil by publishing a book on Secret Remedies, disclosing their composition and showing how most vaunted preparations consisted of very ordinary ingredients quite incapable of fulfilling the claims made for them. But the many millions of dollars spent on these advertisements shows that the evil is unchecked. At the house of commons the minister of health, Sir Kingsley Wood, received a deputation from the parliamentary committee on food and health, which also represented a number of important bodies, commercial as well as professional. British Medical Association, Pharmaceutical Society, National Pharmaceutical Union, Society of Medical Officers of Health, National Association of Insurance Practitioners, Advertising Association, Newspaper Society, Surgical Instrument Manufacturers Association and others. Captain Elliston, M. P., who spoke for the deputation, said that the parliamentary committee on food and health had in preparation for some time the draft of a bill to control the advertisement of medicines and surgical appliances. In 1912-1914 a select committee of the house of commons, at the instigation of the parliamentary committee on food and health, investigated the question and reported in favor of legislation. Then came the war. Several endeavors have since been made to introduce legislation but it had not been possible to make progress with a bill. One difficulty was to secure the agreement of the many interests concerned. The present bill had been discussed with all the important interests affected and a measure of agreement had been reached. The principal objects of the bill were: 1 To prohibit the advertisement of medicines, surgical appliances or forms of treatment as effective for the cure or prevention of certain specified ailments, such as cancer and tuberculosis. 2 To prohibit the invitation to members of the public to obtain the diagnosis or treatment of these ailments by correspondence. The bill also contained clauses safeguarding the legitimate interests of those concerned, including newspapers and religious organizations. Speaking as president of the Advertising Association, Sir John Pybus said that the bill would not affect adversely any legitimate trade interest. The Newspaper Proprietors Association had not committed itself to support the bill, but its representatives had taken part in the drafting. In view of the safeguards for the newspapers there was no need to anticipate any opposition from their association.

In replying, the minister of health said that he greatly appreciated the valuable work done by the parliamentary committee on food and health. Although many newspapers already set a high standard in the matter, legislation was undoubtedly needed. He would have the bill examined and make inquiries as to the amount of support that might be anticipated for it. If this proved satisfactory, the introduction of legislation would be considered sympathetically, if the government's general program of legislation made this possible. It may be commented on this proposal and reply that, while it would be well that unfortunate sufferers from cancer and tuberculosis should be protected against the fraudulent promises of cure, the bill touches only a small part of fraudulent advertising. Evidently the condition requiring the support of the interests concerned does not allow more to be done.

Industrial Accidents The Greater Danger to Young Workers

In his annual report, the chief inspector of factories draws attention to a marked increase in industrial accidents, which numbered 136,858 in 1934 and 113,260 in 1933, and particularly to a high accident incidence among young workers. The number of fatal accidents in the two years were 785 and 688 respectively. The inspector points out that the adult worker has become accustomed to his environment and has—or ought to have—acquired habits of caution. The young entrant finds factory life an entirely new experience and has in addition certain qualities of youth, such as bravado and curiosity, which render him susceptible to accident. It seems that he should have an apprenticeship in safety, just as in productive work. The inspector proposes that during school life there should be instruction in industrial dangers just as there are now in road traffic dangers. Also every entrant into industry should be taken round the factory before he starts work and shown the principal risks. Such a demonstration would be more effective than a book of safety rules. Due selection of the process on which the young entrant is to be engaged is called for and careful supervision during the early period of the employment. The inspector has been long impressed with the number of accidents in which new workers have been allowed to operate machines capable of inflicting severe injury which should be entrusted only to experienced workers. A watch should be kept on young workers during their first year, and those who have incurred an undue number of accidents however trivial, should when possible be transferred to safer occupations.

The accident rate (as distinct from the number of accidents) tends to vary directly with the number employed. The main factor is probably lessened exposure to risk resulting from the shorter hours worked during times of industrial depression. But another influence may be a tendency at such times to discharge the less steady workers, who are more prone to accidents than the others.

HEALTH IN INDUSTRY

Dr J C Bridge contributes to the report a chapter on health. He says that, while undoubtedly industry does produce ill health it is outside the factory that most of the ill health arises. To work for a living in employment giving interest is a healthy occupation but the monotony and the tedium of so many forms of modern industry make one wonder how it is carried on so zealously. Boredom must increase the significance attached to minor sickness and consequently the length of absenteeism. Dr Bridge deprecates the tendency to employ workers under 18 the full limit of legal hours.

An innovation in safety work is the appointment in a factory which already possesses an active safety committee of carefully selected workmen in each department as 'safety associates'. Their duty is to bring to the notice of the safety committee any dangers or risk that otherwise might escape notice. In another factory the safety committee has organized a class of boys for instruction in safety principles and in first aid.

Indian Students in England

In Dr Thomas Quayle's Report on the Work of the Education Department of the Office of the High Commissioner for India for the year ended last September has been published. The number of Indian students at the universities of the United States and on the European continent is estimated at 2000 while the number in the British Isles is nearly ten times greater. There are about seventy Indian women students at British universities and colleges medicine and education being their main subjects of study. The present report confirms the opinion expressed by Dr Quayle in the last few years that there is a steady improvement in the standard of the Indian students who come to this country. The majority are on the whole well

qualified to embark on the courses for which they have come. There have been many academic successes, and the athletic and other distinctions won by Indian students shows that they are taking an ever increasing part in the corporate and social life of the colleges. The large number engaged on postgraduate work reflect the fact that after taking good degrees at home universities they have come here to do advanced or research work for which the necessary facilities are not always available in India. An important change is that most of the students are training in various scientific and technical professions instead of largely confining themselves, as they did too often, to cultural and legal training.

Maternity and Child Welfare

Sir Kingsley Wood, minister of health, addressing the National Council on Maternity and Child Welfare, referred to maternal mortality as one of the most pressing public health problems. On the other hand child welfare work showed steady and satisfactory progress. The high death rates of infants under 1 year which prevailed up to the early part of this century, was a powerful factor in the institution of the child welfare movement. The result had been the remarkable and consistent reduction in those rates from 128 deaths under one year per thousand births a year in the first decade of this century to rates which in the last four years never exceeded 66 and in 1934 fell to the record figure of 59. A striking example of the results that could be obtained by early recognition and treatment was shown in orthopedic work. It had become increasingly clear that cripples were largely made and not born and that many of those congenital defects which did occur were comparatively slight at birth and could be best rectified in the earliest years. The results of improved methods was shown in the marked decline of the more serious crippling defects and in particular of tuberculosis of the bones and joints.

The fact that maternal mortality showed no such decline was a matter of grave national concern. The problem was of great complexity. Maternal mortality occurred among the rich as well as the poor and in the high-class seaside town of Bournemouth was more than in industrial Sunderland depressed by gross unemployment. The number of antepartum clinics had steadily increased and also the number of maternity beds provided by the local authorities. There was much to be said for an improvement in the midwifery service. The remuneration of midwives was low and this reacted on the quality of entrants to the profession and their efficiency. He was examining this question and would receive the views of various important associations and local authorities and would see what could be done.

"The Radium Hen"

An instrument to assist hospitals that have lost or mislaid radium needles has been invented in the National Physical Laboratory. It has been called the 'radium hen' because it clucks like a hen when placed near radium and the nearer it is the more rapidly and excitedly it clucks. It has been used to find a radium needle suspected of having been washed down a hospital sink. Water poured down the sink had been tested for radioactivity without result. Every trap in the waste pipe had been taken out and still there was no trace of the needle. Then the 'radium hen' was tried and quickly led by its clucking to the point in the pipe at which the needle was lodged.

In appearance the instrument is not unlike a garden syringe but behind its brass cased head is a neon lamp and a trail of 'flex' leading to a box of high tension electric batteries. The neon glows when the electric pressure is sufficient to cause a discharge through it. Here the pressure is adjusted so that the lamp will just not light. The radium radiation, as it were, pulls the trigger. The lamp has to be kept covered as it is sensitive to daylight. It therefore cannot be used as an indicator. This is provided by the electric current, which flows

through the lamp when it is alight. This current is converted into sound either by the use of head phones or by a loud speaker, which clicks in correspondence to the flashing of the hidden lamp.

PARIS

June 21, 1935

Law to Check Abuse of Public Hospital Service

One of the members of the French chamber of deputies has introduced a bill to prevent further admissions to the public (free) hospitals of those who are able to pay. During the last few years the public hospitals have been overcrowded. Many persons whose means permitted them to enter private hospitals have been admitted because they wished to be under the care of medical men who are chosen on a competitive basis and who represent the leaders of the profession. The public hospital authorities have admitted many who should have been cared for elsewhere because the hospital budgets were greatly reduced. The medical profession has protested in vain thus far, hence this law will prevent abuse of the privilege to enter free hospitals. A committee will be appointed in each department of France. A representative of the administration and two physicians will constitute the personnel of the committee. Only emergency cases and persons who are proved to be indigent or temporarily without resources will be admitted if this bill becomes a law. After investigation of the individual applicant, a card, valid for six months, will be issued to those who are eligible to enter the free hospitals. The deputy in presenting the bill stated that "everything possible must be done to lighten the burden of a profession that has suffered so intensely and yet has remained faithful to its ideal of helping suffering mankind."

Intravenous Injection of Charcoal

At the March 11 meeting of the Academy of Sciences, a report was made of the results obtained following the intravenous administration of a 2 per cent solution (suspension) of charcoal of animal or vegetable origin. Physiologic solution of sodium chloride was employed as the medium. A hyperleukocytosis is produced, which represents about the double of the normal leukocyte content of the blood. It begins several hours after the injection and reaches its maximum in from six to eight hours, lasting about twenty-four hours. Small daily doses have the same effect as one large initial dose. The smaller the particles, the more lasting the hyperleukocytosis. The favorable action of such injections in infections is due to the resultant hyperleukocytosis.

Sporadic Scurvy in an Adult

At the March 8 meeting of the Société médicale des hôpitaux of Paris an interesting case of sporadic scurvy was reported by Sézary and Joseph. A woman, aged 37, had shown symptoms of scurvy for the eight months preceding admission to the hospital. At the onset the chief signs were bleeding from the gums, pain during mastication, marked weakness and emaciation. Two months later a severe metrorrhagia lasting three weeks and large ecchymoses on the lower extremities were noted. There was also pain and swelling of the joints. The dyspnea on exertion and emaciation were the symptoms especially complained of, when the patient was first seen by the authors. The condition of the gums, the arthritis in the ankle joints and the purpura led to the suspicion of scurvy. The blood examination revealed a secondary anemia, and although the coagulation time was normal the clot formation was abnormal. Eighteen months prior to the onset of the gingivitis and other initial symptoms, the patient had an attack of urticaria and was told not to eat any fruit, vegetables or milk, thus all vitamin C had been eliminated from her diet.

In the discussion, J. Hallé reported two sporadic cases of scurvy in adults. In one of these an elderly man had followed

a diet composed exclusively of macaroni and vegetable soup. Recovery rapidly followed a change of diet in which fresh fruits, vegetables and salads predominated. The second patient was also an elderly man, who had attempted to follow a diet composed of only soup made of bread.

Armand-Dehille recalled the large number of cases of scurvy observed during the World War among retreating Serbian soldiers, who were obliged to live on jam and biscuits. Justin-Besançon called attention to the recent work of American investigators and recommended the use of cevitic acid in the treatment of cases of scurvy.

The Schick Reaction in the French Army

In the January issue of the *Archives de médecine et de pharmacie militaires*, Fricker reports finding the reaction positive in 51 per cent of 7,800 soldiers. Among 212 noncommissioned men, whose average age was 28 years, the incidence of positives was 40.5 per cent and among seventy-six officers, whose average age was 37 years, it was 18.4 per cent. A preceding attack of diphtheria seems not to have any immunizing action. The proportion of positive Schick reactions in soldiers who had diphtheria in infancy was 47.3 per cent.

Indications for Periarterial Sympathectomy

Based on their experience of 546 operations, Leriche and Fontaine, at the March 25 meeting of the Academy of Sciences, reported the following as indications for periarterial sympathectomy. It is especially efficacious in the arteriosclerotic form of arteritis, when thrombosis is absent. In senile arteritis, it is a conservative procedure and may enable one to avoid an amputation.

In thrombo-angitis, ganglionectomy and adrenalectomy are preferable to periarterial sympathectomy. In vasomotor disturbances of the Raynaud type the latter procedure in younger individuals gives excellent immediate and prolonged results. In scleroderma, periarterial sympathectomy is especially indicated when the lesions are recent and localized. The operation is followed by astonishingly good results in posttraumatic sequelae, such as hard edema and painful osteoporosis. In ulcerations of amputation stumps of trophic origin, periarterial sympathectomy is especially indicated. The same is true of leg ulcers, delayed union of fractures and the Volkmann syndrome (when there is no arterial thrombosis).

Cancer of Cervix Following Subtotal Hysterectomy

At the April 1 meeting of the Obstetric and Gynecologic Congress of Paris, Sejournet reported a case of cancer developing in the cervical stump five years after a subtotal hysterectomy for fibroids. He found 302 similar cases, which had been reported since 1926. The majority of these were not seen by surgeons but were recognized when the patients applied for radium treatment.

First Congress of Human and Animal Brucellosis

Representatives of the medical and veterinary schools gathered for the first time in Avignon, June 11, to discuss the relations between the different forms of brucella infections in man and those of animals. The subjects discussed were prophylaxis and treatment of undulant fever, differentiation of the various types of brucella infection, epidemiology of brucella infections in relation to the dairy industry, and legislation on the subject of undulant fever.

Admiral Grayson Elected President of League of Red Cross Societies

At a meeting in Paris at the headquarters of the League of Red Cross Societies, Admiral Cary T. Grayson was elected president, to succeed the late John Barton Payne. Admiral Grayson is eminently qualified to fill this position. He was the personal physician of Presidents Woodrow Wilson and Theodore Roosevelt. He is a commander of the French Legion of Honor.

Cancer Pamphlet for the Public

The league for the control of cancer has recently issued a pamphlet for distribution in every city and village of France, which can well serve as a model for similar organizations in other countries. The different forms of neoplasm are discussed in a way to make the general public grasp the manner in which cancer and sarcoma develop and spread. The necessity of early recognition is emphasized. Next follows the frequency of malignant growth in the world, the causes of cancer, and a discussion of precancerous conditions and the role of personal hygiene in prevention. The remainder of the pamphlet is devoted to a series of excellent photographs of patients with malignant superficial cancers and another series showing the appearance of the individuals following treatment. An outline of the latter is given, also a list of anticancer centers all over France and its colonies where those who wish to have an early diagnosis made can apply. The slogan "Cancer is curable" is stressed. The public is urged to take a more optimistic view of cancer, by a summary of the percentages of cures in various types of malignant disease if the diagnosis can be made before the lymphatics are involved.

Inquiry into Garbage Removal in Berlin

Some time ago a number of workmen engaged in garbage removal complained to the consultation center of the university institute for research on occupational diseases of injuries to health that they thought they were suffering by reason of their employment. A medical inquiry into the conditions under which workmen engaged in garbage removal are obliged to work was instituted. A physician accompanied the garbage wagons on their rounds, in order to become acquainted at first hand with the nature of the work. All loading centers for garbage were inspected. It was found that these workmen are exposed to a health hazard, but no more than groups of workmen engaged in certain other lines of heavy outdoor work. To determine what injuries garbage workmen suffer, 700 were subjected to a medical examination. The workmen presented frequently skin disorders and skin changes, particularly papules and pustules. Comparatively few suffered from hernias, although many were subject to muscular rheumatism, owing to the fact that they were often exposed to inclement weather. Workmen who have been engaged for many years in this type of work show the harmful effects of the dust that rises from dry fine garbage, but no evidence of active tuberculosis could be discovered.

Anteflexion of the Uterus

Many anatomic inquiries have dealt with the question as to why the uterus lies anteflexed. Prof. M. Westenhöfer, anatomist of Berlin, has sought to solve the problem by the application of ontogenetic principles, as expounded before the Berliner Gesellschaft für Geburtshilfe und Gynäkologie. The position of the uterus in the pelvis is dependent on the relation of the pelvis to the spinal column. When man came to abandon the quadrupedal posture and assumed the erect position, only the lumbosacral portions of the spine were erected whereas the sacral portion, firmly united with the pelvis, diverged but slightly from its former horizontal position. Owing to that fact the uterus remained nearly horizontal that is anteflexed. The acetabulum lies vertically under the sacrum in other words, the axis of the ilium forms with the sacrum an angle of nearly 90 degrees, whereas in other mammals the pelvis is shifted more or less caudad. Only in man can one speak of a pelvic arch. If one causes a four-footed mammal to stand erect, the whole pelvis together with the axis of the sacrum and the contents of the pelvis is involved in the process all the parts lie then

vertical to the horizontal line, including the uterus, there is no trace of anteflexion. Hence anteflexion does not depend on the assumption of the erect posture but, on the contrary, in man on the preservation of features of his former quadrupedal posture. Likewise the configuration of the external soft parts particularly the buttocks, is associated with this fact, for it is evident that no animal has buttocks of a form similar to the human type.

Relation of Surgery and Orthopedics

The representatives of surgery and of orthopedics have held different opinions with regard to the recognition of orthopedics as a specialty, and these differences have led to many controversies at congresses. Now it has been agreed that orthopedics shall continue to be recognized in the medical curriculum and as a subject for examination, being considered as a branch subject of surgery, to which must be assigned the dominant position as one of the three principal branches of medicine. As the chairmen of the German Surgical Society and the German Orthopedic Society both admitted to be the case, no sharp differentiation of the fields of activity can be drawn. A rough division, however, may be based on the fact that to surgery belong chiefly those diseases in the treatment of which operative measures stand in the foreground. Hence restorative surgery and fresh injuries, including fractures and sprains, come mainly under the head of surgery, whereas orthopedics comprises principally those cases in the treatment of which bloodless interventions and the use of orthopedic apparatus are commonly preferred.

Defects in Color Vision

For years, Prof. William Trendelenburg, physiologist of Berlin, has been studying defects of color vision, to discover whether in a line of hereditary succession the type of the anomalies remains the same or whether they possibly may alternate with color blindness. In his research a distinction between the rested condition and the fatigued condition was strictly carried out. It was found that a changed reactivity (fatigue) was not an inherent part of the anomaly. Examinations of enzygotic twins revealed plainly that a congenital peculiarity lay at the basis of the changed reactivity also. The various forms of defects in color vision, it was found, do not merge together in a hereditary line, that is particularly true of anomalies in anopia of the same type. If there is a simultaneous occurrence of different forms in the same family, it is evident that there is not a uniform hereditary succession but that a second hereditary predisposition is making itself manifest. These results are in harmony with the theory of Waaler to the effect that a particular hereditary predisposition lies at the basis of each of the four types of defective color vision. For the changed reactivity, however, a special hereditary predisposition may probably be assumed. These results furnish support to the Helmholtz theories of color vision.

Congress on the Circulation of the Blood

The Gesellschaft für Kreislaufforschung held recently in Wiesbaden a joint session with the Deutsche Gesellschaft für Innere Medizin. The opening paper on the main topic, "Circulation and Respiration," was presented by W. R. Hess, physiologist of Zurich. Next in order, K. F. Wenckebach of Vienna discussed the clinical relations of respiration to the circulation. He emphasized particularly the importance of diaphragmatic respiration, on which the thoracic respiration is based. In addition to the costal muscles and the diaphragm the long back muscles (as costal spreaders) exert an essential influence on respiration. Hochrein of Leipzig called attention to the pulmonary circulation.

The second day was spent in joint session with the Deutsche Gesellschaft für Innere Medizin, and the papers presented on aeronautic problems have already been discussed in a previous letter (THE JOURNAL, June 22, page 2279).

Synthesis of Cyclic Compounds

Dr Jose Giral y Pereira, professor of biologic chemistry at the Faculty of Medicine of Madrid, was recently appointed an academician at the Academia Nacional de Medicina. In his speech of entrance to the society, he discussed the ability of animals to synthesize cyclic compounds. He said that the opinion that animals are unable to synthesize cyclic compounds, because of their inability to build the benzene ring, can be maintained no longer. It has been proved that animals synthesize cholesterol, in spite of the fact that they are unable to synthesize tryptophan, lysine, arginine and cystine that is certain amino acids, either cyclic or acyclic. The stability of rings and nuclei depends on the number of atoms in their chains as well as on the presence of antagonistic functional groups of atoms at the ends of an open chain. Protozoa develop normally in a medium which contains only an ammonium salt and carbohydrates, from which compounds they build the cyclic compounds which form the amino acids. The speaker believes that there are specific diastases for the formation of cyclic compounds. The speaker discussed the mechanism of formation of biliary acids from cholesterol. Diseases caused by a retention of cholesterol are the sequels of faulty oxidation.

The speaker discussed also the molecular structure of certain compounds in relation to their activity as carcinogenic substances. He said that the nonhydrogenized benzene compounds of five nuclei are the only types frankly active as carcinogenic agents among the group of coal tar derivatives especially benzopyrene. Cook says that there is a close relation between sterols, biliary acids, sex hormones and carcinogenic substances and that the latter have their origin, in living organisms, in the transformation of hydro-aromatic semisaturated cycles of either sterols, biliary acids or sex hormones into aromatic nuclei with double bonds. The plicenanthrene nucleus in the compound is responsible for the transformation of a physiologic into a pathologic action. Other cyclic bodies built by animals are inositol, several aromatic substances, vitamin A, flavine bases, uric acid and pyridine bases. Birds have the property of synthesizing and eliminating uric acid. Their eggs are poor in purine, but the organism of the birds contains it in abundance. Kellmann of Vienna the first to report on the possibility of the synthesis of cyclic bodies by man, reported the case of a girl who, while receiving a diet without purines showed an increase of 4 Kg in weight in fifty days and eliminated during this time 15 Gm of uric acid probably synthesized by the organism.

Obdulio Fernandez, professor of chemical analysis in the Faculty of Pharmacy of Madrid, discussed the paper of Dr Giral y Pereira. He said that Dr Pictet spent eight years trying to find a reducing agent for hydrogenization of one of the nuclei of nicotine. He found that although both nuclei of nicotine are inert one is more inert than the other. That seems to indicate that the reduction of cyclic compounds is a mechanism of defense of living organisms. The closure of a molecule of dextrose into a molecule of inositol does not require as great an expenditure of energy as that required to burn the whole chain in the molecule of dextrose. In comparing the elimination of indole with that of other aliphatic substances it can be noted that the elimination of aromatic substances is easier and requires the expenditure of less energy than that of compounds of a closed chain. To state that animals transform only compounds synthesized by plants accuses man of a kind of parasitism that really does not exist. With present knowledge it would seem foolish to seek alkaloids in animals. And yet their presence in animals has been verified in the field of forensic chemistry.

History of Ferran's Vaccines

Dr Garcia del Real, professor of the history of medicine at the Faculty of Medicine of Madrid, recently lectured before the Academia Nacional de Medicina of Madrid on the history of Ferran's vaccines. During the cholera epidemic in Spain in 1885 Dr Ferran, who was the municipal physician of Tortosa, came to Madrid and called the attention of the medical profession to the harmlessness and immunizing properties of a vaccine that he had prepared with living *Vibrio cholerae* and the results of which he had already verified, first by experiments and then by immunizing himself, his family and many other persons. Several injections were necessary to develop immunity and Dr Ferran performed about 50,000 vaccinations during the epidemic. The vaccine did not control the development of cholera when given to persons who were in the prodromal stage, but it produced complete immunity in persons free of the disease. Some physicians, especially Drs. Gimeno and Pulido, believed in Ferran's theories but others attacked them to such an extent that the government ordered Ferran to stop his crusade for the prevention of cholera. The number of deaths (160,000) caused by the epidemic would have been greatly reduced if the vaccination campaign had been continued. Two years later, during an epidemic of typhoid, Ferran prepared a vaccine that produced immunity. He also prepared vaccines against plague and tuberculosis. The speaker said that Ferran like Gutierrez of Buenos Aires and Semmelweis, was misunderstood by his colleagues. Ferran, Servetus, Gimbernat and Cajal have been the four most prominent Spanish scientists.

Homage to Dr Gimeno

Pupils and friends of Dr Amalio Gimeno, president of the Academia Nacional de Medicina of Madrid collaborated in organizing a sumptuous celebration at the Academia Nacional de Medicina May 31 in honor of his eighty fifth birthday. The most prominent Spanish scientists and a select group of other notables attended. Dr Gimeno wearing the medal of the Spanish Legion of Honor, presided. Dr Goyanes, ex-president of the Liga española contra el cancer, made the speech of welcome. Dr Simonona read from the works of Dr Gimeno, who was presented during the ceremonies with a gold medal and with the first edition of a book containing his scientific and literary productions. Dr Gimeno was the minister of state during the World War and professor of medicine in the Faculties of Medicine of Santiago, Valladolid, Valencia and Madrid. He is a well known orator and writer on medical, political and socialist topics. His replies to speeches made in his honor were touching, as he is almost blind because of cataract. And yet he still is engaged in scientific work.

Marriages

- ROBERT E. SHOEMAKER, Haddonfield, N. J. to Miss Eleanor Fairlie of Norristown, Pa., April 15, 1933, announced, June 18.
ALBERT LOUIS GUSTETTER, Nogales, Ariz., to Mrs. Rose Sylvia of Hollywood, Calif., in Phoenix, Ariz., April 24.
EDWIN MONROE GRISWOLD, Granby, Conn., to Miss Eleanor Forbes Hodge of South Glastonbury, April 30.
ALLEN RICHARD MORRISON, Maywood, Ill., to Miss Evelyn Marie Herbst at Chicago Heights, July 6.
NAPIER S. ALDRICH, Coldwater, Mich., to Miss Virginia Hague of Columbus, Ohio, June 15.
WALTER M. PFEIFFER to Miss Gertrude F. Martin, both of Quebec, Que., Canada, June 3.
WILLIAM M. COLLINS to Miss Rosa J. Connolly, both of Lowell, Mass., recently.
RALPH F. ALLEN, Milton, Fla., to Miss Eugenia Dillon of Miami, Fla., June 17.

Deaths

Cornelius John Tyson * New York, University and Bellevue Hospital Medical College, New York, 1912, clinical professor of medicine at his alma mater served during the World War, aged 51, consulting physician to the French Hospital, New York, Southside Hospital Bayshore and the Brunswick General Hospital, Amityville, president of the medical board and director of the medical division of St Vincent's Hospital, where he died, June 28

William Dunn Gates * Indiana Pa, Hahnemann Medical College and Hospital of Philadelphia, 1898 past president of the Indiana County Medical Society fellow of the American College of Surgeons, served during the World War at one time county coroner, on the staff of the Indiana Hospital, aged 69, died, June 25, of internal traumatic hemorrhage.

Thomas P Keenan, Lake Geneva Wis, Chicago College of Medicine and Surgery, 1916 member of the State Medical Society of Wisconsin, president and formerly secretary of the Walworth County Medical Society, served during the World War, city health officer, aged 42 died June 15, in the Walworth County Hospital, Elkhorn, of pneumonia

Elliott Knight Dixon, St Louis, Washington University School of Medicine, St Louis, 1915, member of the Missouri State Medical Association and fellow of the American College of Surgeons, served during the World War, aged 44 on the staffs of the Jewish Hospital and St Luke's Hospital, where he died, June 25, of pneumonia

Carlton S L McCullough, Steubenville, Ohio, University of Maryland School of Medicine and College of Physicians and Surgeons, Baltimore 1923, member of the Ohio State Medical Association and the West Virginia State Medical Association, served during the World War aged 41, died suddenly, June 18, of coronary thrombosis

Albert De Kalb Parrott, Kinston N C University College of Medicine Richmond, 1906 member of the Medical Society of the State of North Carolina fellow of the American College of Surgeons, on the staff of the Parrott Memorial Hospital, aged 52, died April 19, of chronic myocarditis

Wilford Alexander Norris, Columbia, Mo, University of Missouri School of Medicine, Columbia 1883 member of the Missouri State Medical Association for eighteen years city health officer on the staff of the Boone County Hospital, aged 77, died May 28, of coronary thrombosis

Martin Yates, Fulton, Mo, Bellevue Hospital Medical College, New York, 1876, member of the Missouri State Medical Association, past president and secretary of the Callaway County Medical Society member of the board of education, aged 83 died April 9, of arteriosclerosis

Vladimir Dmitrievich Sezenevsky, Honolulu Hawaii Military Medical Academy St Petersburg Russia 1893 member of the Hawaii Territorial Medical Association on the staff of the Leahi Home aged 66 died May 2, of a liver abscess, while on a train near Sparta, Wis

Dempsey L Travis, Lakewood Ohio University of Wooster Medical Department Cleveland 1878 member of the Ohio State Medical Association medical officer of the public safety department of Cleveland aged 80, died June 30 of chronic myocarditis and arteriosclerosis

Milton S Smith, La Porte Ind, Chicago Homeopathic Medical College, 1896, member of the Indiana State Medical Association on the staff of the Holy Family Hospital aged 73 died July 3 in the Presbyterian Hospital Chicago following an operation on the prostate

Franklin Sawyer Palmer Seattle Harvard University Medical School Boston 1890 member of the Washington State Medical Association formerly health officer and police surgeon, aged 69 died June 5 in the Providence Hospital of valvular heart disease.

Earle Raymond Van Cott, Salt Lake City Utah Rush Medical College, Chicago 1914 member of the Pacific Coast Oto Ophthalmological Society served during the World War aged 46, died May 14 of angina pectoris

Walter Cyril Steele, Niagara Falls N Y University of Buffalo School of Medicine 1912 member of the Medical Society of the State of New York aged 44 died May 12 of intestinal fistula and pulmonary embolism

James Baruch Hughey Kingstree S C University of Maryland School of Medicine Baltimore 1885 member of the South Carolina Medical Association aged 73 died suddenly June 13 of endocarditis

John Wallis Walker, Winona, W Va., University of Louisville (Ky) Medical Department 1893 member of the West Virginia State Medical Association, aged 78, died recently of cerebral hemorrhage.

William Harvey Dixon, Ayden, N C., Medical College of Virginia Richmond 1901, member of the Medical Society of the State of North Carolina, aged 62, died, May 29 of angina pectoris

Eugene Elmer Kendall, Waterford, Pa, Jefferson Medical College of Philadelphia, 1887 member of the Medical Society of the State of Pennsylvania, aged 74 died, June 11, of heart disease

James Tompkins Leftwich * Highland Springs, Va, Medical College of Virginia Richmond, 1915 president of the county board of health, aged 51, died suddenly, June 6, of angina pectoris

Elmer Gilman Fosgate, Ashburnham, Mass, Dartmouth Medical School, Hanover, N H, 1889 member of the Massachusetts Medical Society, aged 75, died, June 8, of valvular heart disease

John Isaac Miller, Gary, Ind, Illinois Medical College Chicago, 1908, formerly a member of the state legislature in Wyoming aged 57, died, June 13, of chronic myocarditis and endocarditis

Herbert Erwin Phelps * Carthage, N Y Long Island College Hospital, Brooklyn, 1896, aged 63 died, June 11, in the House of the Good Samaritan, Watertown, of cerebral embolism

Georgia Sizer Orvis, Guthrie, Okla, Bennett College of Eclectic Medicine and Surgery Chicago 1900 aged 86 died, May 13, in the Masonic Home for Aged, of chronic myocarditis

Charles L Dohm, Chicago City Minn University of Minnesota College of Medicine and Surgery, Minneapolis, 1896, aged 60 died, May 28 in St Paul, of rheumatic heart disease.

John A Rader * Caney, Kan Eclectic Medical Institute, Cincinnati, 1890, past president of the Washington County Medical Society aged 75 died June 6 of arteriosclerosis

William Henry Parrish, Vallejo Calif Willamette University Medical Department Salem, 1889 aged 87 died, May 18, of cerebral hemorrhage and bronchopneumonia

David F Haagen, York, Pa Jefferson Medical College of Philadelphia, 1908, aged 51 died May 11 in St Peter's Hospital, New Brunswick, of lobar pneumonia

William Kelley Sanborn, Oakland, Calif, University of California Medical Department, San Francisco 1893 aged 69 died, May 24, of chronic myocarditis

William J Waits, Gray, Ga Georgia College of Eclectic Medicine and Surgery, Atlanta, 1895, aged 66, died, April 18, of diabetes mellitus and hypertension.

Jacob De Witt Graham, Springville Iowa Rush Medical College, Chicago, 1891, aged 76, died, June 19, of cardiorenal sclerosis and cerebral hemorrhage

Clarence Williamson Orr, Cincinnati, Miami Medical College Cincinnati, 1883 aged 79, died, June 10, of chronic nephritis and auricular fibrillation

James Phillippe Tamesie, Portland, Ore, University of Oregon Medical School Portland, 1889, aged 73, died, April 29, of coronary thrombosis

Franklin Thomason Beatty, Boston, Jefferson Medical College of Philadelphia, 1885, aged 77, died, April 18, of chronic myocarditis

Benjamin F Owens, Louisville, Ky Jefferson Medical College of Philadelphia 1866 aged 92, died, May 17, of cerebral hemorrhage

John E Thomas, Baltimore Temple University School of Medicine Philadelphia 1912 aged 70 died April 18, of cerebral hemorrhage.

Jacob W Arbogast Bellefontaine, Ohio Eclectic Medical Institute, Cincinnati 1894, aged 78, was found dead June 17, of heart disease

Walter Pollano * Lawrence Mass Middlesex College of Medicine and Surgery Cambridge, 1922 aged 56 died, June 25

Thomas J Russell Perry, Iowa, Missouri Medical College, St Louis 1893 aged 73 died May 1 of cerebral hemorrhage

Arthur S Austin * Aberdeen Wash Detroit College of Medicine, 1886 aged 72 died, May 11, of angina pectoris

CORRECTION

Report of Death—Dr William A Anderson of Glencoe Ala was erroneously reported dead in THE JOURNAL, July 20, page 217 Dr Anderson is alive and in good health

Bureau of Investigation

MISBRANDED "PATENT MEDICINES"

Abstracts of Notices of Judgment Issued by the Food and Drug Administration of the United States Department of Agriculture

[EDITORIAL NOTE The abstracts that follow are given in the briefest possible form (1) the name of the product, (2) the name of the manufacturer, shipper or consigner, (3) the composition, (4) the type of nostrum, (5) the reason for the charge of misbranding and (6) the date of issuance of the Notice of Judgment—which may be considerably later than the date of the seizure of the product]

Mineral Wells Crystals—W E Hoist Chicago Composition Essentially Glauber's salt with small quantities of magnesium calcium and iron carbonates and chlorides For rheumatism indigestion kidney liver skin and blood disorders, etc Fraudulent therapeutic claims—[N J 21810 September 1934]

Heal Kwik Plaster—Andrew J Pontier Clinton N J Composition Essentially a plaster containing rosin wax and starch For boils sores inflammation, sore throat swollen glands etc Fraudulent therapeutic claims—[N J 21814 September 1934]

Jacob Becker's Celebrated Eye Balsam—W M Olliffe Inc New York and Kells Co Newburgh N Y Composition Essentially mercury and finely powdered sand incorporated in fat Fraudulent therapeutic claims—[N J 21818 September 1934]

Beggs Mustorine—S C Wells & Co Le Roy N Y and Mutual Drug Co Cleveland Composition Essentially an ointment of petrolatum containing volatile oils including those of turpentine sassafras cajuput and wintergreen and red pepper with a small amount of ground mustard For sore throat chest colds lame back stiff joints or muscles rheumatism etc Fraudulent therapeutic claims—[N J 21819 September 1934]

G O Remedy—A J Holden Rawlins Wyo Composition Essentially plant drug extracts salicylic acid and water For hay fever itch eczema psoriasis etc Fraudulent therapeutic claims—[N J 21821 September 1934]

Acnoid No 1 and Acnoid Special No 2—Sergeant Acnoid Pharmaceutical Co Inc East Orange N J Composition No 1 essentially salicylic acid and small amounts of salol and camphor in a fatty acid and petrolatum base No 2, essentially salicylic acid zinc stearate and small amounts of salol and camphor in a fatty acid and petrolatum base For skin diseases etc Fraudulent therapeutic claims—[N J 21822 September 1934]

Novonol Ointment—Belmont Co Springfield Mass Composition A local anesthetic such as procaine hydrochloride in a mixture of fatty acids and petrolatum Adulterated because below professed strength and purity, and misbranded because of false and misleading claims to being antiseptic—[N J 21976 September 1934]

Belmont Germicide—Belmont Co Springfield Mass Composition Essentially common salt borax camphor menthol and a small amount of wintergreen For wounds ulcerating corns bunions infections etc Fraudulent therapeutic claims—[N J 21976 September 1934]

Lambert's Syrup—Dr J O Lambert Ltd Troy N Y Composition Essentially chloroform (0.91 minum per fluid ounce) creosote volatile oils including sassafras menthol and wintergreen epsom salt (2.4 per cent) and a small amount of a benzoate with sugar and water Misbranded because chloroform content falsely declared and because of fraudulent therapeutic claims as a remedy for coughs catarrh bronchitis asthma etc—[N J 21979 September 1934]

Fe Sen—Ellis Jones Drug Co Memphis Tenn Composition Essentially plant drug extracts including a laxative with alcohol sugar and water For liver trouble nervous and sick headache indigestion etc Fraudulent therapeutic claims—[N J 21980 September 1934]

Wallace's Liverade—Liverade Medicine Co Fulton Ky Composition Essentially plant drug extracts including a laxative such as cascara sagrada with licorice red pepper sugar alcohol (9.1 per cent by volume) and water For indigestion sick headache fevers chronic constipation piles, etc. Fraudulent therapeutic claims—[N J 21980 September 1934]

Jayne's Brio da Tonie Pills—Dr D Jayne & Son, Inc Philadelphia Composition Essentially an iron powder with calcium and magnesium glycerophosphates copper sulphate and plant drug extracts including red pepper and nux vomica For anemia debility loss of appetite etc Fraudulent therapeutic claims—[N J 21981 September 1934]

Gep Qual Yek Due—Louie Chong Dai Chinese Herb Co San Francisco Composition Essentially a small amount of plant or animal material with alcohol (29.5 per cent by volume) sugar and water Misbranded because alcohol content was greater than declared on label, and because of the fraudulent representation that the stuff was a remedy for rheumatism—[N J 21982 September 1934]

Khylex—Khylex Chemical Co Alexandria Va. Composition Essentially sodium hypochlorite sodium hydroxide sodium carbonate, common salt and water For skin eruption etc. Fraudulent therapeutic claims—[N J 22021 September 1934]

L B J Cough Syrup—Little Brown Jug Inc., Sinking Spring, Pa. Composition Essentially plant drug extracts including wild cherry tar sugar alcohol and water For coughs croup whooping cough bronchitis, etc. Fraudulent therapeutic claims—[N J 22022 September 1934]

Correspondence

MOTORING AND SCIATICA

To the Editor—The following aids are helpful for automobile drivers with sciatic neuritis 1 A snug fitting elastic stocking for the thigh 2 A rubber sponge fastened to the floor of the car with a piece of leather for the heel of the right foot to rest on, or a small rubber invalid's cushion for the left foot 3 Have car springs oiled every month

A T BLACHLY, M.D., Portland, Ore.

GYNECOMASTIA DURING HYPER THYROIDISM

To the Editor—I have just read Dr Starr's article "Gynecomastia During Hyperthyroidism" in THE JOURNAL, June 1, page 1988, and noted the rareness with which this condition has been observed. It may be of interest that I have recently observed a case of bilateral, symmetrical hypertrophy of the mammary glands in a man, aged 35, with classic exophthalmic goiter, the hypertrophy of the glands having been noticed for two months, while the subjective symptoms of hyperthyroidism had been noticed for nine months. Following operative treatment for the goiter, along with improvement of his other symptoms, the enlargement of the mammary glands receded to normal.

D L CURB, M.D., Galveston, Texas.

AUSCULTATION OF ABDOMEN

To the Editor—In the article by Wakefield, Mayo and Barger entitled "Ileus Associated With Transient Renal Insufficiency. A True Enterorenal Syndrome" (THE JOURNAL, June 22, p 2235) there appears to be no mention of stethoscopic examination and sounds heard over the abdomen in any one of the ten cases reported. It is very likely that such an examination was performed in each case for audible peristaltic sounds and was very likely absent in all, so that it was omitted in the report. The importance of listening for peristaltic sounds in the differential diagnosis of paralytic and mechanical ileus was deeply impressed on me by Dr Roger T Vaughan at the Cook County Hospital whenever the problem presented itself. Especially is this of value when the patient has had one or more previous abdominal operations. Dr Vaughan insisted, and probably still does, that one listen with the stethoscope over each abdominal quadrant for at least three minutes in all suspected cases of ileus in an attempt to determine whether the ileus is paralytic or mechanical, nonsurgical or operative. In almost all cases of nonmechanical ileus, one type of which is described by Wakefield and his associates in the article, no peristaltic sounds are audible. In mechanical ileus, especially if seen within the first twenty-four hours and particularly so in the first twelve hours of the obstruction, the peristaltic sounds are intensified up to the point of the obstruction and from there on disappear completely. Mechanical tinkling is diagnostic of complete mechanical ileus. The point which I wish to emphasize is that, in examination of acute conditions of the abdomen, auscultation to determine the presence or absence of peristaltic sounds and their character, if audible, should be performed and become a routine part in all case records of such nature.

NATHAN FLAXMAN, M.D., Chicago

BRONCHIAL ASTHMA IN CHILD

To the Editor—My son, aged 4 years has bronchial asthma. The father has sinusitis and bronchial asthma which has been largely overcome in the climate of Arizona together with conservative nasal surgery. The mother is living and well but her sister has hay fever of the perennial type. The grandfather on the father's side has had bronchial asthma and hay fever for practically his entire life. The family history otherwise is essentially negative regarding allergy. The birth of the patient was normal and his weight at birth was 10 pounds (4.5 Kg). During the first six or eight weeks of life there was definite pylorospasm associated with projectile vomiting controlled with atropine and postural feedings. The child had enteritis at 3½ years with uneventful recovery. For the past two years the patient has had coincident with occasional attacks of bronchitis a definite asthma which lasts from twenty-four to forty-eight hours and ceases with improvement in the bronchitis. During the past twenty-four hours he has had an attack of bronchial asthma without the usual coincident acute bronchitis to usher it in. There seems to be nothing of particular note in his physical examination except probable adenoid hypertrophy as evidenced by a slight tendency to mouth breathing at night. His tonsils are essentially normal with no history of tonsillitis. Roentgen examination of the chest is negative for thymic enlargement. I would appreciate discussion of a conservative approach to this case. I am particularly interested in the value of high voltage roentgen therapy over the tracheobronchial lymph nodes as an adjunct to conservative surgery of the pharynx. Please omit name.

M D Arizona

ANSWER.—The facts stated describe typical bronchial asthma as it occurs in children: the antecedent history of allergy in the father, grandfather and aunt, the history of pylorospasm and enteritis, then the attacks of bronchitis, so often mislabeled asthmatic bronchitis, which finally turned into frank bronchial asthma. Too often these symptoms in children are diagnosed as bronchitis and asthmatic bronchitis and are merely treated symptomatically and no effort is made to find the cause of the trouble.

The attacks become more and more severe, the bronchitic element less and less, and the asthmatic symptoms become more and more striking until finally the family and the doctor realize that they are dealing with a case of bronchial asthma, which, in truth, was bronchial asthma from the beginning and should have been so recognized.

The experience of those specializing in the treatment of bronchial asthma and other allergic diseases has shown that in these children the best method of treatment is to find and then eliminate the cause or causes as completely as possible. Furthermore, in cases in which elimination of the cause has not been possible, desensitization to the cause has given excellent results in the hands of most allergists.

The procedure, then, is to have the boy "gone over" thoroughly from the allergic standpoint. The history should be searched carefully for etiologic factors, such as food factors, house dust and weeds. Complete skin tests should be carried out for pollens, epidermal substances, such as hair, dander and feathers, for all foods containing protein that the boy has eaten and for miscellaneous substances such as orris root, cottonseed, flaxseed and house dust.

After this procedure, elimination of the positive factors should be carried out thoroughly and desensitization should be done where indicated. Any other method of treatment, while helpful, does not begin to give the successful results that may be obtained in most cases by adhering to the usual allergic procedures. It is true, however, that attention must be paid to the general hygiene, especially the teeth and tonsils, but removal of tonsils and adenoids should be carried out only if indicated for pathologic changes in the tonsils and adenoids or because they harbor foci of infection. Operative procedures on the tonsils and adenoids or on the nose rarely give more than temporary relief in cases of bronchial asthma. Likewise, high voltage roentgen therapy over the tracheobronchial lymph nodes is not especially indicated, although it is true that a measure of relief is obtained in some cases.

It is important to have the child tested out thoroughly and promptly. In this way it is usually possible to avoid emphysema and pigeon breast, which too often occur in these asthmatic children.

COLON SPASM AND MUCOUS COLITIS

To the Editor—I have at present a man under my care, aged 38, single, who gives a history of having had influenza in 1918 and since then he states he has not had a natural bowel movement. He has had to resort to colonic irrigations for the last nine years in order to obtain relief. Numerous roentgen examinations, complete blood chemistry and gastro-intestinal series have been done in four of the largest hospitals in New York, all of which were negative, as far as the findings of any pathologic changes was concerned. In fact the physical examination with the exception of the chief complaint shows no signs of abnormality. The patient is well nourished and is able to go about his work daily. There are no abdominal signs present. He appears to be very nervous and talks much about his condition. A tentative diagnosis of paralytic ileus, possibly neurotic in type has been my contention. I have tried pituitary injections, diathermy, strychnine and many other therapeutic measures to build up his resistance and nervous system but without results. There is a definite mucous colitis present with reverse peristalsis and some spasticity. I note that Osler describes similar cases as ileus hystericus. The patient has seen many physicians during this long time without relief. Can you give me any idea as to what the real condition is and what therapeutic measures should be instituted if any? Is surgery advisable.

M D New York

ANSWER.—The description of the case suggests a tendency to colon spasm and mucous colitis. While this condition may in some cases be largely a neurosis, it is by no means merely psychic in nature. It is more likely to be a neurosis of the vegetative nervous system. It is sometimes maintained by reflex irritation from the generative organs, most especially in the female. It may be an expression of allergy. It is in a large proportion of cases accompanied by a tendency to stasis in the proximal colon. In any case, no matter how the spasm originates it tends to produce a vicious circle of stasis in the proximal colon with spasm in the distal colon, a condition that might be termed "stasis spasm" because it is self-perpetuating, the spasm leading to stasis and the stasis—making the colon contents more irritating—leading to spasm. The therapy should include the determination and elimination of the cause, if this is possible. It needs unlocking the spasm, which is often best done by oil enemas taken at bedtime for several successive evenings. It needs lessening the irritative quality of the stools by softening them with liquid petrolatum or in obstinate cases by the use of castor oil. The diet needs to be of the "smooth" type, i. e., as free from mechanically irritating particles as possible. As this diet is essentially constipating and as such a diet may maintain the stasis spasm, it is necessary for the patient to make persistent efforts to change the diet to a more or less "high residue" type as soon as or whenever his condition shows evidence of improving. Sedatives rather than stimulants for the central nervous system are likely to be of advantage, such as the administration of bromide. Antispasmodics of the type of atropine are likely to be of advantage to relieve acutely painful paroxysms, and this may be well combined with analgesics, such as acetylsalicylic acid and phenobarbital. Surgery is not advisable unless a definite malformation, correctable by it, is discovered.

TREATMENT OF AMEBIASIS ECHINACEA

To the Editor—Will you kindly inform me on the subject of the treatment of *Amoeba histolytica* and *Giardia*? A patient, who for five consecutive years has been under the continuous treatment of several physicians has still a positive stool test and marked clinical symptoms. The treatment consisted of repeated courses of carbarsone, vioform, chiniofon by mouth and enema, emetine, neosarphenamine, iodoxyquinolin sulphonic acid, mercurochrome and iodine retention enemas. A druggist recommends Lloyd's Echinacea. What kind of drug is this? Is it specific? What are the Lloyd preparations? Please omit name.

M D, California

ANSWER.—A case of amebiasis persisting for five years under such treatment as mentioned suggests first a serious question as to whether one is dealing with *Endamoeba histolytica* at all. This matter should be verified by authoritative examination. The next step would be a detailed roentgen study of the large intestine and sigmoidoscopic examination to determine the nature, location and extent of any lesions present. If *Endamoeba histolytica* is proved present the treatment recommended would be a course of carbarsone, 0.25 Gm twice a day for one week, followed after one week by six retention enemas on alternate nights each consisting of 200 cc. of 1 per cent carbarsone in 2 per cent sodium bicarbonate solution, introduced slowly and retained over night. This retention enema should be preceded by a cleansing soda enema two hours earlier. Again, after a ten day interval, a course of vioform 0.5 Gm. twice a day for ten days should be given by mouth. Persistence of *Endamoeba histolytica* after this treatment would suggest strongly the need of surgical attention to some deep focus.

So-called specific medicines are prepared by Lloyd Brothers, Pharmacists, Inc., Cincinnati. Echinacea is described as a liquid preparation made from the dried root of *Echinacea augustifolia*, the purple cone flower of our Western prairies, in unstated dilution in 65 per cent alcohol. According to John Uri Lloyd, Echinacea was used by the American Indians and taken up by the early settlers in the West under the name "Indian Head Root." Based on this use it was exploited first as a secret remedy ("Meyer's Blood-Purifier") and then as a proprietary panacea. C. G. Lloyd (1885) determined its botanic place, and the eclectic professors King, Goss, Webster, Ellingwood and Felter studied its clinical applications. The root contains resins and no alkaloids, according to Heyl and Staley, 1914. Several proprietary preparations of it have been praised for sialagogue, diaphoretic, antiseptic, stimulant and general alterative effects, but no good evidence of its value has been published and the claims appear to be extravagant. The drug was disapproved by the Council on Pharmacy and Chemistry in 1909. Among medical men in general, echinacea remains without use or repute.

DERMOGRAPHISM

To the Editor—A man aged 30 weighing about 190 pounds (86 kg) and standing 5 feet 10 inches (178 cm) tall and apparently in perfect health came to me recently complaining of severe dermatographia. His past history relates only his having the usual childhood diseases and when about 10 years old he suffered from what he was told was severe pyelitis of both kidneys. He made an uneventful recovery from this and has never been troubled since. He has had fairly severe attacks of acute arthritis and had all his upper teeth removed about five years ago with no return of his arthritis. At present he is in excellent health and works hard daily without any complaints except suffering from this dermatographia. The physical examination reveals nothing pathologic. I have seen the patient scratch himself anywhere on the arm, legs and face (his hands, body and feet are immune from this) and immediately raise large red welts. This particularly bothers him while shaving; his face becoming streaked red and burning just after a shave. He must shave always at night and then retire. The condition will persist for two or three hours and then disappear entirely. Can you suggest what the cause of this might be and what I might do for him?

JOHN F. MAURER, M.D., Acosta, Pa.

ANSWER—Dermatographism is caused by a sensitization of the skin to stroking. Other forms of trauma cause less reaction. The work of Ebbecke, Lewis and Grant, Gidemista and Scheffler, Torok, Lehner and Urban has shown that the trauma releases an irritating substance in the skin, which causes a localized transient edema, a wheal. This resembles the wheal of urticaria except that it often does not itch.

The name urticaria factitia given to this condition is a misnomer, for it is evidently an entirely different condition. Many patients with urticaria have no dermatographism and on the other hand, most sufferers from dermatographism have no urticaria.

Dermatographism is often associated with mental disorders, epilepsy, idiocy, insanity or catatonia. It is seen also in cases of toxemia, lead poisoning and alcoholism. It is more marked after physical or emotional strain and in women at the menstrual periods. Many cases of dermatographism, however, like the one described show no other abnormality. It has been suggested that excessive histamine production in the intestine may be responsible in some of these cases. Endocrine imbalance is an important factor in some cases.

If the cause can be discovered, indications for therapy are plain, but in many cases this is impossible. General hygiene is of course the first indication. If no cause can be discovered, reduction of intestinal histamine may be attempted by implantation of *Bacillus acidophilus*. For temporary relief, cold applications are most effective, according to Reznick (Klinische Studien ueber Dermatographism *Wien Klin Wchnschr*, Oct 29 1914, p 1424). Epinephrine and therefore probably ephe-drine are less effective. The effect of cold can be counteracted, however, by heat, which, applied within a certain time, brings back the wheals. In the case under discussion therefore cold should be maintained for some time. Possibly the use of ephe-drine before shaving and the application of cold afterward may have a better effect.

The patient can be thankful that he did not live during the days of the witchcraft hysteria. If at that time it was discovered that the word Satan could be written on a person's skin and would remain there (dermatographism), the condition was apt to be cured promptly by the application of heat—that is, by the persons being burned alive.

TREATMENT OF SYPHILIS

To the Editor—Wassermann fast acquired syphilis was discovered incidentally in a white man aged 30 by a routine blood Wassermann reaction (four plus both antigens). The probable date of acquisition of the infection was at least seven or eight years prior to the institution of treatment. No primary or secondary lesions had ever been noted. The case is not congenital as proved by investigation of the parents, and apparently not contagious at the time of marriage five years ago, as the wife and one child aged 4, are Wassermann negative. Treatment has been intensive and unremitting for two years. Chief reliance has been on neocarsphenamine alternating first with courses of bismuth salicylate in oil intramuscularly and then mercurous intravenously. No injections from treatment were allowed. Repeated Wassermann examinations during the two years have shown no change, although the patient now subjectively has never been better and there is no evidence of visceral syphilis on careful physical examination. Neurosyphilis has been ruled out by spinal fluid examination and clinical observation. Questions arise as to further management of the case. Is one justified in continuing intensive treatment longer than two years? Should the patient be further treated or merely observed? If treatment is indicated, what is the best choice of drug or drugs, dosage and time interval between courses? Please omit name.

M. D. New York

ANSWER—Assuming that the patient has a nonsymptomatic Wassermann-fast syphilis, the treatment described could be rated as adequate to a latent infection in accordance with the experience of the Cooperative Clinical Group and the United States Public Health Service with Moore as spokesman.

A year's complete rest from all treatment may result in a gradual approach to serologic negativity, and certainly nothing more than periodic observation, particularly of the cardiovascular system, should be required in a case of this sort. It is true that occasional courses of a heavy metal, particularly bismuth, are favorably regarded in the management of these patients, but this, together with the other described methods of dealing with Wassermann-fastness in latency described in various textbooks, need not be considered until after a prolonged rest period.

LETHAL DOSE OF AMYTAL

To the Editor—Recently I was called to see a young married woman, who one hour previously had swallowed with suicidal intent twelve amytal tablets (Hilly) containing 1½ grains (0.1 Gm) each. She was comatose when I arrived. Respiration was sighing and shallow, the pulse was weak and thready, the temperature was normal, there was no nausea or vomiting and the pupils were not contracted. A stomach tube could not be introduced nor could an emetic be administered. Caffeine and later strychnine hypodermically brought her out of her comatose condition. When she was able to swallow 1 ounce (30 cc.) of whisky was given. What is the lethal dose of amytal and the attendant symptoms? Please outline treatment. The patient made a good recovery but may there not be some untoward symptoms following an experience of this kind? I would greatly appreciate any suggestion offered. Kindly omit name.

M. D. Ohio

ANSWER—A cursory study of the literature does not permit as yet the categorical statement of the lethal dose of amytal. According to Sollmann (Manual of Pharmacology ed. 4 1932) the generally fatal dose of amytal is from 2 to 3 Gm. The treatment of such cases requires evacuation of the stomach, carried out with due precautions against aspiration of fluid and leaving in the stomach cathartics such as magnesium sulphate or fluidextract of cascara. It might also be well to leave hot black coffee in the stomach after the washing. Caffeine or strychnine should be used even in heroic doses, to antagonize the depression of the nervous system. Elimination might be favored by aminophyllin or another xanthine diuretic and by dextrose phleboclysis. Artificial respiration with oxygen inhalation should be used on the appearance of enfeeblement of respirations. During the stage of reaction with the development of pulmonary complications, the treatment is that of pneumonia. Picrotoxin also is useful.

ILL EFFECTS OF HABITUATION TO BARBITAL

To the Editor—Can you give me any information about the ill effects if any of the continuous use of sodium amytal? I have a friend who is neurotic and feels he must take from six to 15 grains (0.4 to 1 Gm.) daily to control a nervous nausea. He fears that it may hurt him. Of course he has a drug habit from it which he cannot give up as yet. Can you tell me what harm either functional or organic may come from the habit? I have looked through our medical library and in the recent *Cumulative Index Medicus* and have found no information and no doctor in Rhode Island seems to know definitely of any bad effects although all of them say that an amytal drug habit is bad.

GEORGE J. McCURRY, M.D., Providence, R.I.

ANSWER—The ill effects of barbital derivatives, including isoamylethylbarbituric acid, or amytal, may be grouped under three headings: (1) idiosyncrasy, (2) overdose, and (3) habit formation. In the case under discussion it may be stated definitely that the patient is now suffering from a drug habit. While so far as available literature goes, surprisingly little

harm seems to have followed the habitual use of amytal, there is a decided danger in this habit formation, arising chiefly from two sources. The one is that all forms of chronic drug narcotism that have been studied for a sufficient length of time are known to lead inevitably to mental and sometimes physical deterioration. Secondly, there is always danger of a fatal overdose being taken when the patient finds that the dose to which he is habituated no longer suffices to produce the desired degree of comfort.

FOR DYNE

To the Editor—What is For Dyne of the First Texas Chemical Manufacturing Company Dallas Texas?

L N

ANSWER.—According to the firm's catalogue, For-Dyne consists of Formasal, $5\frac{1}{2}$ grs., Phenacetine, 1 gr., and Caffeine Citrated $\frac{1}{2}$ gr. The ridiculousness of the product is shown by the description of Formasal, which, according to the manufacturers, is "a chemical manufactured by fusing Salicylic and Acetic Acids with Phenolphthalein after which Colchicine Salicylate is added to reinforce action." What would result from the fusing of these three substances one can only guess. It seems hardly possible that there would be a concern in the days of more enlightened chemical procedure that would offer a product to the medical profession with such an unscientific statement. For-Dyne then, according to the manufacturer's statement, may contain acetphenetidin caffeine citrate, colchicine salicylate, salicylic acid, acetic acid and phenolphthalein, the latter three being a fusion mixture!

PREVENTION OF IMPETIGO IN
MATERNITY HOSPITAL

To the Editor—Will you please give me the latest routine bathing care of new-born babies in maternity hospitals with special reference to prophylaxis against impetigo. Has any method other than 0.5 per cent ammoniated mercury in oil been successfully used?

ERNEST L. SCRABLE M.D. Gary Ind

ANSWER.—Five per cent ammoniated mercury is most satisfactory for the initial anointing of the body of the new-born infant. Of course proper aseptic technic should be used by all attendants coming in contact with the infant at this time and during its subsequent hospitalization. Persons handling the infant should wear clean gowns and masks and have freshly washed hands. The nurse should carefully scrub her hands before starting the bath, which should be a daily warm sponge bath. Special attention should be given to cleaning the axilla groins and interdigital spaces. Due care should be exercised not to traumatize the skin by rough handling or rubbing.

POLLENS IN MICHIGAN

To the Editor—In THE JOURNAL April 13 page 1359 appeared a query regarding the climatic conditions in Alpena Mich. with regard to hay fever and in the April 27 issue page 1486 appeared an article on pollen studies by O. C. Durham. In this connection I will give some information obtained from the weather bureau and will quote from the communication from Mr. A. L. Weisner meteorologist U. S. Department of Agriculture.

No statistics on the pollen contents of the air are available for this place but the prevailing direction of the winds during the summer season would indicate that the amount must be very small. The prevailing direction during the summer months is almost a loss up between south east and northwest. However the detailed records show that during the daylight hours from about 9 a. m. to 8 p. m. when winds are more active and pollen is apt to be carried the winds are almost steady from the southeast while during the damper night hours when the winds are lighter the prevailing direction is northwest.

Alpena is so situated with respect to Lake Huron that all winds with easterly components from north-northeast to south-southeast are direct lake winds and must cross over from 60 to 120 miles of water before reaching Alpena. Even north and north-northwest winds are almost lake winds as they cross but short stretches of land before reaching Alpena.

It is not probable that northwest winds which would have in cross Lake Superior would bring an appreciable amount of pollen. Hence the only pollen-bearing winds would be westerly and southwesterly. Winds from both of these directions are not prominent during the summer months.

The following table obtained from a ten year average gives an estimate of how many hours the wind may blow from each direction during the summer months.

	N	NE	E	SE	S	SW	W	NW	Total
June	59	40	61	192	49	70	91	158	720
July	60	31	42	178	56	91	95	191	744
August	60	39	55	163	70	8	99	180	744
September	54	35	56	143	58	100	114	160	720

I would add that Alpena is the location of the only government weather bureau in the northern half of lower Michigan. The records of our weather bureau show that the prevailing wind at 6 p. m. is north-east, which is a lake wind and should be free from pollen.

E. S. PARKINSTER M.D. Alpena Mich

Medical Examinations and Licensure

COMING EXAMINATIONS

AMERICAN BOARD OF OPHTHALMOLOGY The Cincinnati examination previously announced will not be held. The next examination will be given in St. Louis Nov. 18. Application must be filed before Sept. 15. Sec. Dr. William H. Wilder 122 S. Michigan Ave. Chicago.

AMERICAN BOARD OF OTOLARYNGOLOGY Cincinnati Sept. 14. Sec. Dr. W. P. Wherry 1500 Medical Arts Bldg. Omaha.

AMERICAN BOARD OF PEDIATRICS Seattle Aug. 8 Philadelphia Oct. 10 and St. Louis Nov. 10. Sec. Dr. C. A. Aldrich 723 Elm St. Winnetka Ill.

AMERICAN BOARD OF RADIOLOGY Detroit Dec. 12. Sec. Dr. Bjrl R. Kirkin Mayo Clinic Rochester Minn.

ARIZONA Basic Science Tucson Sept. 17. Sec. Dr. Robert L. Nugent Science Hall University of Arizona Tucson.

NATIONAL BOARD OF MEDICAL EXAMINERS The examination will be held in all centers where there are Class A medical schools and five or more candidates desiring to take the examination Sept. 16-18. Ex. Sec. Mr. Everett S. Elwood 225 S. 15th St. Philadelphia.

NEVADA Reno Aug. 5. Sec. Dr. Edward E. Hamer Carson City.

NEW HAMPSHIRE Concord, Sept. 12-13. Sec. Board of Registration in Medicine Dr. Charles Duncan State House, Concord.

NEW YORK Albany Buffalo New York and Syracuse Sept. 16-19. Chief Professional Examinations Bureau, Mr. Herbert J. Hamilton 315 Education Bldg. Albany.

OKLAHOMA Oklahoma City Sept. 10-11. Sec. Dr. James D. Osborn Jr. Frederick.

PUEBLO RICO San Juan Sept. 3. Sec. Dr. O. Costa Mandry Box 536 San Juan.

WISCONSIN Basic Science Madison Sept. 21. Sec. Professor Robert N. Bauer 3414 W. Wisconsin Ave. Milwaukee.

Connecticut Homeopathic Report

Dr. Joseph H. Evans, secretary, Connecticut Homeopathic Medical Examining Board, reports the written examination held in Derby, March 12, 1935. The examination covered 7 subjects and included 70 questions. An average of 75 per cent was required to pass. Two candidates were examined, both of whom passed. The following school was represented:

School	PASSED	Year Grad	Per Cent
Hahnemann Medical College and Hosp. of Philadelphia		(1933)	83.1
839			

Colorado April Report

Dr. Harvey W. Snyder, secretary, Colorado State Board of Medical Examiners, reports the written examination held in Denver, April 2, 1935. The examination covered 8 subjects and included 80 questions. An average of 75 per cent was required to pass. Two candidates were examined, both of whom passed. Five physicians were licensed by endorsement. The following schools were represented:

School	PASSED	Year Grad	Per Cent
Northwestern University Medical School		(1935)	87
Osteopath*			83.5

School	LICENSED BY ENDORSEMENT	Year Endorsement Grad of
Hahnemann Medical College and Hospital Chicago		(1903) Iowa

Book Notices

Living with the Weather By Clarence A. Mills M.D. Ph.D. James T. Heady Professor of Experimental Medicine University of Cincinnati. Cloth Price \$1.50 Pp 206 Cincinnati Caxton Press 1934

Dr. Mills has been studying for the past six years "climatic and weather effects" and has made "continuous observation of patients in clinic and hospital" and "of laboratory animals under controlled conditions." One need not read far in the book to suspect that Dr. Mills feels that Walter Hines Page understated the influence of climate when, in a letter to a friend in 1913, Page said regarding life that "half of it is climate, a fourth of it is occupation, the other fourth companionship. And the climate (with what it does) is three fourths of companionship." "Weather men," says Dr. Mills, when they speak of weather, mean the behavior of such factors as temperature, pressure, moisture, wind, and sunshine over relatively short periods of time. Climate on the other hand, refers to the sum total of weather over long periods of time. And according to Dr. Mills, weather and climate are potent, though often unrecognized factors in practically everything mankind does or doesn't do. No attempt is made by Dr. Mills to present in this book the evidence from which his conclusions are drawn, but he states that "the analysis is based on a prolonged study of the subject and practically all statements made have a certain amount of definite scientific evidence as a foundation." It was Mark Twain who observed that everybody talks about the weather but nobody does anything about it. Dr. Mills talks about the weather and also calls attention to the need of doing something about it—including further study of the part it plays in human affairs, further attention to indoor atmospheric control and further efforts toward better control of the effects of climate on man that would involve finding the set of environmental conditions best suited to his needs. This volume should prove to be of interest to physicians and public health workers in general.

Making Our Minds Behave By William S. Walsh M.D. Cloth Price \$2.50 Pp 277 New York F. J. Fulton & Company Inc. 1935

Dr. Walsh's book is a popular book of advice and suggestions intended to aid the reader in "getting more out of life," to use the author's words. A variety of subjects are treated, ranging from the initial chapter on "Mental Engineering" to a final chapter on "Expressing Ourselves." This last chapter is a dissertation on the art of making speeches. Chapter headings include "Remote Control," "Secondhand Thinking," "Removing the Mask" which may be translated to mean, respectively, "Some Unconscious Determinants of Behavior," "Prejudices and Superstitions" and "Defensive and Compensatory Behavior." Other chapter headings are less ambiguous, as "The Art of Concentration," "Making Good on the Job," "On Being an Executive" and "Can We Take It?" The author modestly states in the preface that he makes no pretensions toward any systematic presentation of theory of behavior but wishes merely to offer "more or less elementary suggestions which the writer believes to be sound." This is exactly what he does, but it is something of a question as to how helpful such a presentation can be. The work is descriptive and exhortatory. While occasional references are made to dynamics of behavior, such references are too vague to be understood by the lay reader. The author is indefinite where he does refer at all to the common psychological concepts on which understanding of behavior is based, viz., "he tends to develop a sort of super-ego which fashions ideals of personal conduct, which acts as a censor of his desires and actions" (p. 23). The style, though popular, is cumbersome and involved. The author is markedly repetitive. The book is overburdened with slang. There are innumerable and frequently rather useless references, of which the most flagrant noted reads "There are many good advisers—Lao-Tzu who, incidentally, anticipated many of the tenets of Christ, Confucius, Aurelius, Epicurus, Epictetus, Seneca, Descartes, Pascal, Kempis, La Bruyere, Bacon, Montaigne, La Rochefoucauld, Amiel, Emerson, to mention a few." The book is full of such padding, and could well be reduced to half the present size without loss of content.

The author is doubtless more helpful in his personal contacts with his patients than he could possibly be with this book, which is tedious largely on account of the stylistic defects referred to. It will not be helpful to neurotic individuals, because it does not offer them understanding of the sources of the difficulties referred to. It may be helpful to some persons who require only friendly encouragement, but the publishers are hardly justified in the announcement on the jacket of the book to the effect that the work "lifts psychology and psychoanalysis out of their technical terminology and presents them clearly and in simple language." While some psychological concepts are dealt with, one could hardly obtain the feeblest understanding of psychoanalytic psychology from the book. The author is much more modest in his claims than are his publishers.

Arbeit und Gesundheit. Sozialmedizinische Schriftenreihe aus dem Gebiete des Reichsarbeitsministeriums. Herausgegeben von Professor Dr. Martin Heck. Ministerialdirigent im Reichsarbeitsministerium. Heft 25. Nerven- und seelische Störungen bei Teilnehmern am Weltkrieg. Ihre ärztliche und rechtliche Beurteilung. Von Dr. Karl Weller. Oberregierungsmedizinrat bei der Versorgungsärztlichen Untersuchungsstelle München. Teil II. Geisteskrankheiten und organische Nervenerkrankungen. Paper Price 8.50 marks Pp 314 with 30 illustrations Leipzig Georg Thieme 1935

Weiler contributes the twenty-fifth number of *Work and Health*, edited by Martin Heck. It consists of an analysis of the nervous and mental disturbances in association with the World War. After an introduction as to how this work was carried out, Weiler discusses dementia praecox (schizophrenia). This chapter is divided into three parts: dementia praecox in general, influence of war and dementia praecox, and finally the conclusions. The second chapter takes up the manic depressive psychoses and consists of a discussion of manic depressive psychoses in general and in association with the World War, followed by conclusions. The third chapter deals with epilepsy and is divided into two parts: epilepsy as an individual entity and the influence of the war on epilepsy. The fourth chapter discusses nervous and mental diseases of syphilitic origin. This is divided into a general discussion of dementia paralytica and tabes dorsalis and the various syphilitic nervous and mental diseases in relation to the war. The fifth chapter considers other organic diseases of the central nervous system, such as multiple sclerosis, epidemic encephalitis and syringomyelia. The sixth chapter deals with the influence of power and force on the peripheral nerves, the spinal cord and the brain. There are a summary and an appendix at the end of the book. Many of the author's conclusions are open to question and discussion. There is almost no bibliography. The book does not offer much to the student interested in these subjects.

Handbook of Anesthetics. By J. Stuart Ross M.B. Ch.B. F.R.C.S.E. and H. P. Fairlie M.D. Anesthetist to the Western Infirmary, Glasgow. With a chapter upon Local Anesthesia by W. Quarry Wood M.D. F.R.C.S.E. Assistant Surgeon Edinburgh Royal Infirmary. Fourth edition. Cloth. Price \$4 Pp 299 with 66 illustrations. Baltimore William Wood & Company 1935

The preparation of this edition has been the sole responsibility of H. P. Fairlie. Anesthetic agents and methods of their administration that are in general use in Great Britain are described. The equipment used differs considerably from the equipment commonly in use in the United States and Canada and should be interesting to members of the profession in this country on that account. Stress is laid in the first chapters on the fundamentals underlying the absorption and physiologic action of anesthetic drugs. Shock in relation to anesthesia is adequately discussed in chapter 2. In chapter 7 the newer basal narcotics tribrom-ethanol (Avertin) and evipan sodium are described. Ether is recognized as the most dependable and safest anesthetic agent for the majority of operative procedures. The dangers associated with administration of chloroform are well outlined. The importance of maintaining an adequate airway during administration of an anesthetic by inhalation is stressed. One page is devoted to a description of Waters' carbon dioxide absorption technic. Accidents encountered, and methods of avoiding them and of treating them, are outlined. A chapter discussing the choice of anesthetic is limited to the anesthetics producing general anesthesia. The next chapter deals with local anesthesia and the following chapter with spinal anesthesia.

The Biochemistry of the Eye By Arlington C. Kruse M.A., Ph.D., M.D. Instructor in Ophthalmology The Johns Hopkins Medical School. The Wilmer Ophthalmological Institute The Johns Hopkins Hospital and University Monograph No. 2 Cloth. Price \$3.25 Pp 264 with 17 illustrations. Baltimore The Johns Hopkins Press London Oxford University Press 1934

Ocular biochemistry has been largely a neglected field until recent years. In this book the author has attempted to review somewhat critically the more important and more trustworthy papers that have appeared, mostly in the last thirty years. The book is essentially a review of the biochemical literature pertaining to the eye and should serve as a convenient reference source to researchers in this field. It can be read profitably only by those who have a ready grasp and appreciation of modern biochemical theory and methods. The author reviews the literature on the chemistry of the external secretions of the eye, conjunctiva, sclera, cornea, uveal tract, retina, aqueous humor, vitreous humor and lens. The literature related to the biochemistry of the eye and published up to and including 1933 is considered. It is probable that much of the quantitative data considered in this work will have to be revised, because many of the biochemical methods that were used are not specific or truly quantitative. The reader may conclude after reading this book that, although it appears that a great amount of time and effort has been spent in work on the biochemistry of the eye, but little is known that is at present of much benefit in considering the various pathologic processes of the eye. While this is probably true, books of this type are useful in their attempt to correlate scattered knowledge and thus may serve to point the way for future work in this difficult field.

Hospital Accounting and Statistics. A Manual for American Hospitals Authorized for publication by the Trustees of the American Hospital Association upon recommendation of the Council on Community Relations and Administrative Practices. Cloth. Price \$1 Pp 85 Chicago American Hospital Association 1935

The committee of the American Hospital Association to be credited with this book states that the purpose is to suggest practical ways by which (a) the administrator can use accounts to control his institution and to interpret his results to others, and (b) the bookkeeper or accountant can accumulate and present useful information with a maximum of clarity and a minimum of routine labor. It successfully carries out the purpose of the committee. It is a manual for the hospital bookkeeper and as such is useful for the hospital administrator. It is neither a textbook on bookkeeping nor a book of sample forms nor a textbook on hospital administration. This book will be an aid to all bookkeepers and administrators.

Studies on Cell Growth (Part II). The Growth in Vitro of Normal Mammalian Cells and of Mouse Cancer Cells (Carcinoma Sarcoma) in Neutral and Immune Media (Serum Plasma) By M. J. A. des Ligneris M.D. L.M.S.S.A. No. XXXIV Vol. VI Publications of the South African Institute for Medical Research. Edited by the Director. Paper. Pp. 313 322 with 109 illustrations. Johannesburg South African Institute for Medical Research 1934

The purpose of this work is to decide the controversy between Lumsden and Ludford. According to Lumsden there are specific anticancer substances formed in animals, which are immunized by inoculation with tumor tissue. The action of these serums is highly specific according to Lumsden. The specificity against the malignant cells was demonstrated by this author in tissue cultures in which he found that the malignant cells were picked out and rapidly killed and the non-malignant cells remained more or less undamaged. Ludford on the other side, came to the conclusion that those cells which were considered by Lumsden to be cancer cells in the tissue cultures were not malignant cells but stroma elements. In order to settle this question Des Ligneris inoculated sheep with tumor material from mouse carcinomas and with normal mouse organs and compared the growth of mouse carcinoma tissue and mouse sarcoma tissue as well as of normal mouse kidney, liver, lung and spleen in serum or plasma, which was obtained from the injected animals with the growth in normal sheep serum or plasma. The results were that the antibodies that had developed in the serum of sheep injected with mouse carcinoma tissue had only antispecies characters and no kind of specifically antimalignant characteristics. The author obtained the same effect on mouse carcinoma or mouse sarcoma cells in

vitro whether the serum or plasma used originated from a sheep injected with normal mouse organs or with mouse carcinoma. Furthermore, the effect on normal mouse cells in vitro was the same whether antmouse sheep serum was used that was produced by inoculation of normal mouse organs or of mouse carcinoma. There are illustrations of tissue cell for demonstration.

Guiding Your Child Through the Formative Years From Birth to the Age of Five. By Winifred De Kok M.R.C.S. L.R.C.P. Cloth. Price \$2 Pp 191 New York Emerson Books Inc. 1935

The author discusses in a clear, concise manner fears, tantrums, habits, freedom, play, independence, sex, education and the various problems with which one is daily confronted in the rearing of children. Having been trained in psychoanalysis, she attacks many of the problems of childhood from the psychoanalytic point of view and she uses the experiences in the rearing of her own children as examples of proper management. While it is impossible to agree fully with the methods outlined and many of the statements, the book in general should be found useful. Those concerned with child management will find much that is of interest.

Die unsichtbaren Krankheitserreger filtrierbare Viren. Ein Lehrbuch für Ärzte und Tierärzte. Von Dr. Josef Baló o. ö. Professor der pathologischen Anatomie und Pathohistologie an der Franz-Joseph-Universität Szeged. Paper. Price 24 marks. Pp 311 with 42 illustrations. Berlin S. Karger 1935

In the present German edition the author has rewritten and brought down to October 1934 the material included in the Hungarian edition, which appeared in 1931. The book is divided into two sections. The first consists of a brief review of the available information concerning the general characteristics of filtrable viruses and the second, which is the main part of the work, deals with most of the important virus diseases of man and animals and a few representative diseases affecting fish, insects and plants. The individual diseases are well arranged in groups according to the author's idea of classification: (1) pox diseases of man and animals, (2) herpes and herpes-like diseases, (3) neurotropic filtrable viruses, (4) organotropic viruses, (5) diseases giving the picture of a general septicemia and (6) viruses associated with proliferative conditions. The discussions in the main are limited to concise reviews of the literature and are followed in each instance by an extensive bibliography, in which an occasional important omission has been noted. One chapter is devoted to the filtrable forms of the tubercle bacilli and to bacteriophage. The details of technical procedures are not generally emphasized except for an appendix dealing with filters and filtration. Considering the fact that there are available relatively few books dealing with the rapidly accumulating information on the important subject of filtrable virus diseases, this manual is a contribution of some value in this field.

Key Catalogus of Parasites Reported for Carnivora (Cats Dogs Bears etc.) with Their Possible Public Health Importance. By C. W. Stiles and Clara Edith Baker U. S. Treasury Department Public Health Service National Institute of Health Bulletin No. 163 (Continuation of Hygiene Laboratory Bulletin Services) Paper. Price 20 cents. Pp. 913 1223 Washington D. C. Supt. of Doc. Government Printing Office 1935

The present bulletin is part 8 of the well known host catalogue being compiled by Stiles and his co-workers. Such compilations will be of great assistance to parasitologists, but it is to be regretted that the data are given in such an abbreviated style that it is often difficult to secure information on a desired subject.

Festschrift. Ino Kubo zu seinem 60. Geburtstag (26. Dezember 1934) von seinen ausländischen Freunden gewidmet. Cloth. Pp. 378 with illustrations. Tokyo The Herald Press Ltd. 1934

This book contains fifty-eight rather short articles of clinical and practical nature by European and American authors on diseases of the nose, throat and ear and their complications. The book is issued in celebration of the sixtieth anniversary of Ino Kubo, professor of otorhinolaryngology in the University of Fukuoka, Japan. The larger number of articles by far are in the German language. Various European countries are represented and there are two American contributors. The book will be of interest to specialists in the diseases with which it deals.

Medicolegal

Workmen's Compensation Acts Trauma and Arthritis

—As the result of a cave-in in the mine in which Duchant was working he fractured several ribs and two of the dorsal vertebrae. He was hospitalized for two and one-half months and his employer paid him compensation. At the time of the accident, however, he was suffering from an advanced and quite generalized progressive hypertrophic arthritis of the thoracic and lumbar spine. When he was discharged from the hospital his employer put him at light work which he performed with great difficulty because of pain in his back and shoulders caused by a stiff or "poker" spine. Alleging that the accident had aggravated his arthritic condition, he brought proceedings under the Minnesota compensation act but the industrial commission denied him compensation. He then appealed to the Supreme Court of Minnesota.

When Duchant, said the Supreme Court of Minnesota was discharged from the hospital according to medical testimony, roentgenograms indicated that the injury suffered in the cave-in had healed and that the condition of his spine was no different from what it would have been had he suffered no industrial injury. In fact, one physician testified that the hospitalization had been beneficial to the arthritic condition. Other physicians testified that the stiffness of Duchant's spine was due to the progress of the arthritis and that the injury contributed nothing to his present condition. Duchant contended that his case came within the doctrine announced in several Minnesota cases that where a hernia develops from strain or injury, suffered in the course of employment a preexisting weakness or susceptibility to hernia on the part of the worker would not bar compensation. But, answered the Supreme Court, the case at bar is easily distinguishable from the cases cited. Here we have a condition, well advanced at the time of injury which according to the testimony of disinterested physicians was neither aggravated nor caused by the injury. In addition there is credible testimony to the effect that the arthritic condition was benefited by the hospitalization made necessary by the back injury.

The Supreme Court accordingly affirmed the action of the industrial commission denying compensation to the workman.—*Duchant v. Oliver Iron Mining Co. (Minn.)* 256 N. W. 905

Pharmacists Degree of Care Required—The plaintiff was suffering a skin irritation from poison ivy. Her physician prescribed a preparation containing sugar of lead, which she applied to the inflamed area. When she went to her pharmacist to have the prescription refilled, he advised her to stop using sugar of lead and sold her a preparation that he himself manufactured. She applied his preparation, and the inflamed skin became blacker and blacker. When the plaintiff called the attention of her pharmacist to this, he advised her to keep on using his preparation. Not until after she had used two and one-half jars of it did he advise her to consult a physician. The physicians whom she consulted were able, by a painful nerve wrecking process, to remove the greater part of the blackness in her skin, but at the time of the trial there was still a dark spot on the plaintiff's breast, which would be permanent unless she submitted to a skin grafting operation. She sued her pharmacist.

At the trial, the pharmacist-defendant testified that he manufactured the preparation that he sold the plaintiff and that it contained sulphur, oil of wintergreen, vaseline and lanolin. According to his testimony, he told the plaintiff at the time that if she used his "skin cure," not to use it in connection with sugar of lead. The plaintiff testified however, that when she purchased his "skin cure" she had already been using the sugar of lead preparation for several days, that she told the defendant that she had been doing so, that he told her not to use any more of it, and that she used none after she began the "skin cure." The jury returned a verdict in favor of the plaintiff, and the defendant moved for a new trial, basing his motion in part on the claim that the court should have sustained his

demurrer to the plaintiff's evidence. The trial court conceded its supposed error and for that and other reasons ordered a new trial. The plaintiff then appealed to the Supreme Court of Kansas.

It was urged on behalf of the plaintiff, said the Supreme Court, that the defendant's demurrer could not be sustained, since the plaintiff's evidence showed negligence on the defendant's part. With this the Supreme Court agreed. The defendant, said the court, was a registered pharmacist, who was selling drugs and compounding medicines. The general rule is that a registered pharmacist is required to use great care in the sales he makes. It was a question of fact whether the defendant, when he sold his "skin cure," explained to the customer that sugar of lead could not be used and that it must be thoroughly washed out of the flesh before the "skin cure" was applied. The defendant's "skin cure" contained sulphur, the inevitable reaction of which would be to cause blackness, as the defendant well knew. When the blackness appeared and the plaintiff called the defendant's attention to it, he told her to keep on using his preparation and the blackness would come off. She followed his advice, and the area to which the "skin cure" was applied became blacker and blacker. Even then the defendant told the plaintiff that she should keep on using his remedy, that it would finally remove the blackness.

The Supreme Court of Kansas quoted with approval the rule laid down in 55 Am. St. Rep. 251, in a note to *Howes v. Rose* as follows:

In the discharge of their functions druggists, apothecaries and other persons dealing in drugs, poisons and medicines are required not only to be skillful but also exceedingly cautious and prudent in view of the terrific consequences which may attend the least inattention on their part. The highest degree of care known among practical men must be used by them to prevent injury from the use of their compounds and they are held to a special degree of responsibility corresponding with their superior knowledge and are generally held liable for the slightest negligence.

In this case, the pharmacist defendant did not exercise the care required of him in the sale of his "skin cure." He knew the effect of the combination of the substances of which it was made up and his customer did not. He persisted in telling his customer to keep on using the preparation and that it would finally remove the darkness. Such conflicts as there were in the evidence were such as must be determined by a jury.

For the reasons stated and others, the judgment of the trial court was reversed and the cause remanded for a new trial.—*Fuhs v. Barber (Kan.)*, 36 P. (2d) 962

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Macrocytic Anemia Following Use of Hair Dye—Baldridge discusses three cases of macrocytic anemia in women who had dyed their hair just before the application of permanent waves. In one of these the temporary changes in the blood were typical of aplastic anemia. It is essential that more cases be studied in order to determine the exact relationship between the dye and the blood changes. The part played by the permanent wave must also be established. Patients having pernicious anemia are likely to lose pigment from the hair at an early age so that they have this added cause for using hair dye. Therefore the presence of a macrocytic anemia in a patient with dyed hair does not establish a relationship between the two conditions. It is possible that the substance which caused the anemia was not the original chemical compound applied to the hair but rather some product that resulted from heating the initial compound.

Neurologic Aspect of Leukemia—Schwab and Weiss cite the clinical course of an unusual case of acute lymphatic leukemia. The presenting manifestations were facial diplegia and a spinal fluid under elevated pressure, containing 2,000 cells and increased amounts of protein. The usual clinical manifestations including the blood picture, developed later over a period of ten weeks. Only about 25 per cent of cases in which there is histologic evidence of leukemic infiltration of the central nervous system exhibit neurologic signs. An analysis of the records of 334 cases of leukemia in Boston revealed an incidence of 20.5 per cent with neurologic signs, excluding retinal lesions. The frequency of neurologic complications in the acute and chronic and in the lymphatic and myelogenous types of leukemia was about the same. The most frequently observed neurologic signs were unilateral or bilateral palsies of the seventh and sixth nerves with less frequent involvement of the fifth, eighth, ninth, tenth, eleventh and twelfth nerves. Absent deep reflexes, pyramidal signs, paresthesias and signs of meningeal irritations have also been encountered. The neurologic signs and particularly involvement of the cranial nerves often exhibit rapid fluctuations. In 73.6 per cent of thirty-four

cases the spinal fluid showed abnormal changes, as indicated by increased cell count, increased protein content and elevated pressure. In view of the frequent involvement of the central nervous system, systematic neurologic examination of the patients and study of the spinal fluid may be of aid in the diagnosis and management of patients with leukemia.

Syndrome of Superior Cerebellar Artery—Davison and his associates cite nine cases of closure or obstruction of the superior cerebellar artery. Homolateral signs and symptoms due to involvement of the cerebellar lobes or the brachium conjunctivum were present in six cases. Involuntary movements of the nature of tremors were noted in only three. Contralateral sensory disturbances were of the dissociated or syringomyelic type and consisted of hemihypalgesia and hypothermesthesia of the face and body. All other modalities of sensation were intact. Such spinothalamic sensory disturbances were present in four cases. In the cases with spinothalamic involvement the lateral parts of the medial lemniscus (spinothalamic component) were diseased as a result of thrombosis of the superior cerebellar artery. In addition to the foregoing symptoms and signs, which are typical of the syndrome of the superior cerebellar artery and its branches, there were other neurologic disturbances such as diminution to absence of the deep reflexes, weakness of the extremities, vomiting, dizziness and dysarthria. In some cases the signs of cerebellar involvement and sensory disturbances could not be elicited because the patients were in an unconscious state as a result of closure of the superior cerebellar artery or because these signs were obscured by other cerebral lesions. Complete obstruction of the superior cerebellar artery (in two cases) destroys the brachium conjunctivum, the mesencephalic root of the fifth nerve, the spinothalamic component of the medial lemniscus, the lobulus anterior, lobulus simplex, lobulus ansiformis, crus I and lobulus floccularis and part of the cerebellar nuclei (dentate, emboliform and globose nuclei). The lobulus II, vermalis, lobulus IV, vermalis and lobulus C₂ vermalis in these cases are spared unless both mesial branches of the superior cerebellar artery are pathologically affected. In the cases of incomplete closure of the superior cerebellar artery, the extent of destruction of the respective structures depends on the degree of the vascular obstruction. In two cases there was involvement of the nuclei of the sixth and seventh nerves probably due to an anomalous distribution of the superior cerebellar artery. In one case there was occlusion of the branch of the superior cerebellar artery which supplies essentially the brachium conjunctivum and the lateral part of the medial lemniscus. In only one case was there selective involvement of the dentate artery, a branch of the superior cerebellar artery.

Tryparsamide in Treatment of Dementia Paralytica—Solomon and Epstein present an analysis of the effect of tryparsamide therapy in a series of eighty-one cases of dementia paralytica in which treatment was begun between the years 1923 and 1930 and in which the condition was determined in 1933. Some of the patients received other forms of antisyphilitic treatment (exclusive of fever therapy) prior to or during treatment with tryparsamide. Clinically, in thirty-four patients the condition was considered to be arrested, in twenty-four to be stationary and in twenty-three to be unimproved. In the

course of the years, fourteen patients died, but in only five cases did death appear to be due to unarrested dementia paralytica. The spinal fluid became normal in thirty patients and was greatly improved in thirteen, moderately improved in eight and unimproved in twenty-nine. There were sixty-four patients in the series who received no other treatment than by tryparsamide. In eighteen of these the spinal fluid became normal, in ten it was greatly improved, in seven it was moderately improved and in twenty-eight it showed no change. A specimen of the fluid could not be obtained in one case. The period elapsing between the beginning of treatment and the time when the spinal fluid became normal varied from less than a year to more than nine years. The number of injections of tryparsamide given up to the time when the fluid became normal varied from twenty to 230. No significant difference in results was found in patients receiving tryparsamide alone and in those receiving other types of antisyphilitic treatment, other than fever therapy in conjunction with tryparsamide. Seventeen patients of the series who did not respond satisfactorily to tryparsamide were subsequently given fever therapy, with strikingly beneficial results. The spinal fluid became normal in twelve patients, was greatly improved in three and was moderately improved in two, whereas before fever therapy the spinal fluid was unimproved in fifteen and only moderately improved in two. The clinical improvement was equally striking. Before fever therapy fourteen patients were considered to show no improvement. After fever therapy eight showed the disease to be arrested, and in six it was stationary. Before fever treatment, in three patients the disease was considered to be stationary. In two of these it was later considered to be arrested without showing notable defect, and in one the condition remained unchanged. The results of tryparsamide treatment in this series compared with the results in a series of 173 dementia paralytica patients treated with malaria did not differ to an extent that can be considered significant.

Quinine Therapy in Multiple Sclerosis—Brickner has employed quinine hydrochloride for five years in treating patients with multiple sclerosis. The forty-nine patients had a total of 308 symptoms. The majority (about 73 per cent) of the symptoms of a duration of two years or less have improved. There was improvement in about 44 per cent of the symptoms of longer standing. Thirty-five symptoms have regressed during treatment. Only seventeen new symptoms have appeared in the whole group and of these only nine were permanent. In twenty-five patients the condition is in a state of remission or they have shown marked improvement and are working or able to work. Of these, twenty are free from incapacitating symptoms and five are almost free. None who were able to work prior to treatment are now incompetent to do so. The condition in ten is apparently in a state of arrest, though the patients are incapacitated to a greater or lesser degree, two appear to be emerging from this state into one of improvement. Eight are worse than they were prior to treatment. Of these, three have died. An additional patient, in whom regression of the multiple sclerosis did not occur, died of pneumonia. All but two of those who have experienced remissions or improvements have maintained them. The dosage of quinine hydrochloride must be determined separately for each patient. As much quinine should be given as is possible without cinchonism. The administration of quinine must be continued indefinitely. The medication is given orally, in the form of quinine hydrochloride. When improvement cannot be obtained, it is worth while to try to arrest the process.

Uterine Cancer—Plass believes that every patient with abnormal vaginal bleeding should be examined bimanually. If the cervix appears benign but does not respond to the usual treatment for cervical erosion, biopsy is demanded. Supravaginal hysterectomy should never be employed for the treatment of supposedly benign uterine lesions, unless the cervix appears normal. The cervix after such an operation constitutes a source of danger, since carcinoma may develop later. Ordinary vaginal and abdominal total hysterectomy do not constitute adequate treatment for cervical cancer, except possibly in very early cases in which the diagnosis can be made only microscopically. Operative intervention in even early cases of cervical carcinoma is justified only if the operator is prepared to remove the upper third of the vagina and the parametrium on each side practically to the pelvic wall by the radical hysterectomies of Wertheim or Schauta. Such operations have a primary mortality of from 10 to 20 per cent, and there are many who feel that all groups of cervical carcinoma should be treated by radiation therapy. Proper radiation treatment consists in the use of both high voltage x-rays and radium as soon as a positive diagnosis has been made. Abnormal bleeding from the uterus itself demands diagnostic curettage with microscopic examination of the curettings. Complete hysterectomy should be performed for adenocarcinoma of the uterus. In certain instances radium and x-radiation may be employed successfully, but this method of treatment has not yet obtained wide acceptance.

Wilms' Tumor—Priestley and Broders believe that probably the most common malignant growth that affects the kidneys of children is Wilms' tumor. Sixty-five cases of this tumor observed at the Mayo Clinic are reviewed. Thirty-seven of the patients were in advanced stages of the disease at the time of the original examination, and they received irradiation or symptomatic treatment alone, the remaining twenty eight patients underwent operation and in twenty nephrectomy was performed. An abdominal mass was the first abnormality noted in 40.5 per cent of the cases, and it was present at the time of examination in all but one case. Pain and hematuria as the presenting symptoms occurred in 28.9 and 17.4 per cent, respectively. The tumor is usually sharply demarcated from the renal substance, which it displaces and distorts, eventually pushing up under and distending the capsule of the kidney. The tumor may be roundish or nodular and on cut section may present a glistening appearance varying from white to brown. It may be lobulated, is usually solid and yet resilient and not infrequently gives evidence of hemorrhagic, cystic or necrotic degeneration. Microscopically all Wilms' tumors contain areas of glandular tissue ranging from ill defined to clear cut acini comparable to those seen in the average adenocarcinoma. Intimately associated with the acini are hyperchromatic round, oval or spindle cells that resemble those of fibrosarcoma or myosarcoma. Wilms tumors are highly malignant. The effect of irradiation is evidenced histologically and grossly by disintegration and necrosis, or by no change whatever, that is, the cells are either destroyed completely or are entirely unaffected. The proper treatment of these tumors should include both irradiation and at an appropriate time, surgical removal. Although one patient has lived for thirteen and one half years following nephrectomy, without receiving any irradiation, the remarkable immediate effect of roentgen therapy on highly malignant tumors of this type renders this form of treatment a valuable adjunct in combating these growths. The length of life from the onset of symptoms until death was very short for the group of patients who were in the advanced stages of the disease and who received only symptomatic treatment. The group of patients who were treated

by irradiation and nephrectomy survived approximately twice as long as the group treated by operation or irradiation separately. Both radium and high voltage roentgen therapy have been used, and sometimes the two may be used for the same patient. A large rubber tube may be left at the time of operation for the purpose of inserting radium directly into the wound during the immediate postoperative period. The general principles involved in the surgical removal of Wilms' tumors are similar to those employed in the extirpation of any malignant renal tumor. The usual posterolateral incision will generally give adequate exposure. Care should be taken to remove all the perirenal fatty tissue possible, as this may be involved by the neoplasm. One should feel for extension along the renal pedicle or retroperitoneal lymph nodes and remove any involved portions if possible. If a few involved lymph nodes remain that cannot be removed, it may be advantageous to place a large rubber tube in this region for the purpose of inserting radium directly into it. Of the forty-four patients who were traced up to the present time, forty are known to be dead. Of the twenty patients who underwent nephrectomy, fifteen are dead, four are living and one was not traced. Of the four patients who survived nephrectomy, only two have survived for any appreciable length of time (13.2 and 32 years, respectively). The other two patients were operated on too recently (six months ago) to permit any conclusion regarding the final result.

Acid Medication in Treatment of Bacilluria—Crance and Maloney used nitrohydrochloric acid successfully in the treatment of five cases of bacilluria. They administered it four times a day in doses of 10 minims (0.6 cc). They have used 4 drachms of nitrohydrochloric acid (not the dilute) and enough water to make 4 ounces (120 cc). One drachm of this mixture in two thirds of a glass of water followed by a full glass of water was given the patient after meals and late at night. The treatment is presented for use in bacilluria of the *Escherichia* variety. Nitrohydrochloric acid reduces the pH to 5 or below in apparently less time than the ketogenic diet and can be administered to the patient without hospitalization and without change in the ordinary diet. Urinalysis, regularly done, in all cases thus far treated has failed to show any damage to the kidney by the consistent absence of albumin and casts. One of the patients, in whom the ketogenic diet failed recovered under the nitrohydrochloric acid treatment. The authors continue this medication for about one week after the culture has become sterile. They have treated three cases of the aerogenes variety which, on acid therapy alone, have become symptom free and pus free but have not yielded sterile culture of the urine.

Diagnostic Significance of Lead in Body—The investigation of Myers and his associates in 500 cases not known to be associated with lead exposure has pointed out various syndromes that may be associated with the "subchronic" type of lead poisoning. Common sources of poisoning, such as foods, drugs and environment, are discussed. One should be on the alert for the possible presence of lead in drinking water, fruits and vegetables. People suffering with obscure gastro-intestinal and cardiovascular disturbances should be examined with the greatest care. Early symptoms that are of importance are loss of appetite, nausea, weariness, constipation, headaches, eye symptoms and circulatory manifestations. For the present, the laboratory investigator and clinician should certainly give attention to all values of more than 50 micromilligrams of lead per liter of urine. About 20 micromilligrams per liter is probably somewhere near the expected limit. In the examination of blood, it is believed that 24 micromilligrams of lead per hundred cubic centimeters covers the patients of the "subchronic" type and that 6 micromilligrams is probably a value somewhat nearer that which should be expected. In the case of hair, it appears that lead finds its way with a great deal of difficulty into the hair, and, when lead is found it may be of diagnostic significance depending on the habits of the patient. Under the present mode of living lead undoubtedly plays a part in many other diseases and should always be given consideration when the clinician is unable to place his finger immediately on some definite syndrome.

Convulsions in Infancy—Brown reviewed 2,279 consecutive records, over a period of thirty-eight and one-half months, in babies less than 2 years of age, finding 400 cases in which there were convulsions immediately prior to or during the hospital stay. Acute infection alone accounted for 30 per cent of the convulsions, with pneumonia, the acute disorders of the upper respiratory tract and sepsis being the principal offenders. The hemolytic streptococcus was responsible for the majority of the septic cases, being closely followed by the pneumococcus and Staphylococcus aureus. Acute intestinal disorder, or alimentary intoxication, accounted for only 27 per cent of the total, with convulsions usually an indication of impending death. Acute disease of the central nervous system contributed 15.5 per cent to the total, with meningitis responsible for most of the cases. The influenza bacillus, the pneumococcus and the tubercle bacillus were the principal etiologic agents. Most of the remaining cases were due to acute encephalitis, secondary to lead, to pertussis and of undetermined origin. Infantile tetany represented 11.3 per cent of the series. Tetany was found to be comparatively frequent in the first four months of life, and uncommon after 1 year of age. Rickets was commonly found in the spasmophilic infant, the incidence increasing with the age of the patient. Similarly, as the infant with latent tetany grew older, acute infection was increasingly apt to be the activating agent. The highest incidence of tetany occurred at a double peak, in winter and early spring. Cerebral birth injury is responsible for only 8.5 per cent of the entire series, although in the neonatal period it is the chief offender. Intracranial hemorrhage is most often the result of birth injury but may be due to hemorrhagic disease of the new-born or fetal erythroblastosis. Cerebral deficiency was found in 9.5 per cent of the convulsive cases and was ordinarily the sequel of birth injury. The tentative diagnosis of epilepsy was made in only 1.5 per cent of the series, because of the lack of chronicity in many cases, which may later prove truly epileptic, and the fact that encephalograms revealed cerebral deficiency in a large number that might otherwise have been called idiopathic epilepsy. Lead poisoning often with encephalitis, accounted for 2.3 per cent. Among the less frequent causes of convulsions are congenital abnormality of the heart, sinus thrombosis, subdural hematoma, congenital syphilis and other miscellaneous conditions, in several of which the convulsions were terminal accompanying a secondary infection. Sodium bicarbonate may be a dangerous drug, as two cases of alkalosis with convulsions occurred in infants to whom it had been administered therapeutically. No cases were observed in which enlarged thymus, teething, constipation, worms or pharyngitis could be held solely accountable.

Treatment of Psoriasis—Owing to the burning pain at the site of injection and the number of injections required in the treatment of psoriasis with alcoholic and formaldehyde suspensions of scales of psoriasis Panja and Maplestone decided to cut out a piece of tissue from psoriasis lesions and make an emulsion of it for injection. Their idea was that the parasite, if it is a filtrable virus will be found not only in the scales but also deeper down in the dermis. This probability they state, is supported by the fact that the epidermal changes have been shown to follow changes in the dermis, such as dilatation of the vessels and elongation of the papillae. These pathologic manifestations suggested that the filtrable virus might be present in the corium in a more virulent state than in the more or less dry epidermal scales. They select an acute or a subacute early patch and dab it with rectified alcohol, then a small piece of the diseased skin to the depth of the corium is snipped off. The piece is weighed and mixed with pumice-stone dust and crushed in a sterile mortar until a uniform paste is produced. A few drops of physiologic solution of sodium chloride may be necessary to make a good paste. The paste is mixed with a measured quantity of physiologic solution of sodium chloride to make up the suspension to the strength of 10 mg in 1 cc. It is filtered through an infusorial earth filter and the filtrate thus obtained is filtered again through sterilized Pasteur-Chamberland L3 candles, and 0.05 per cent phenol is added to the final filtrate. The initial dose was 0.1 cc. and it was injected intradermally. The injections were repeated every third or fourth day the dose being increased each time by 0.1 or 0.2 cc. up to 1 cc. When the dose reaches 0.5 cc subcutaneous injection is better, as by this means the pain of intradermal infiltration is avoided. A course of from ten to twelve injections was given as a rule and if necessary, this was repeated after a fortnight but only in a few cases was a second course necessary. There was no reaction or pain following injections. Twenty-eight cases were treated by the method. Four were quite cured, eight were nearly cured only a few minute spots being left, two cases were apparently cured but relapses took place after three months and they are now improving on another course of injections, three cases did not respond to treatment and one flared up after two injections. The authors obtained equally good results with an autogenous filtrate or one from some other patient.

Detection of Chloroform in Vaccine Lymph—Shah describes a method for detecting chloroform in vaccine lymph. About 5 cc. of absolute alcohol is put in a glass test tube. A current of air (supposed to contain traces of chloroform) is passed through it for a few minutes. About 2 cc of a solution of beta naphthol in a strong solution of potassium hydroxide is added. This is heated to 50 C in a water bath. If chloroform is present a blue or greenish blue color will develop. The author believes that the method will be of considerable help in determining the time lymph should be subjected to aeration after chloroform has been used.

Staphylococcal Pneumonia Among Infants—Smith reports the instances of four infants born in July in a maternity hospital who died of pneumonia within four days of one another. Three of the children became ill within twenty-four hours after leaving the institution, although no abnormality was observed at the time of dismissal, and the other one died in the hospital. The duration of illness in each case was about two days. At necropsy, which was held in two cases, the cause of death was shown to be staphylococcal pneumonia, and a pathologic feature was that in both instances consolidation was on macroscopic examination confined to a single lobe, thus simulating acute lobar pneumonia. From swabs taken from infants in the hospital, six of whom were suffering from catarrhal symptoms, profuse growths of *Staphylococcus aureus* were recovered from the nasal and faucial passages in practically all cases. Examination of a control group of infants in another institution demonstrated the unusual incidence of the staphylococcal infection among the children in the infected hospital. It was ascertained that within the previous fortnight an infant had died of a phlegmonous abscess, that three mothers and an infant had suffered from suppurative mastitis, and that among the infants there had been an unusual prevalence of minor septic skin lesions followed by a number of cases of mild catarrh of the upper respiratory tract. Further, six cases of mastitis after dismissal were discovered among fifty-five mothers who left the hospital during July and the first week of August. With the possible exception of the phlegmonous abscess, the author considers all the foregoing cases, including the four fatal pneumonia cases, to have been different manifestations of staphylococcal infection and to form one epidemiologic group. The spread of the disease was possibly facilitated by the nature of the temporary sleeping arrangements provided for the infants.

Tuberculous Ultravirus—Sanarelli and Alessandrini report a series of experiments on the tuberculous virus, using double collodion sacs for both in vivo and in vitro investigations. They attempted to determine the extremes and limits of use of the collodion sacs for this type of experiment. It was confirmed that the "tuberculous protogenes" developed in the external cells of the double collodion sacs either in the peritoneal cavities of rabbits or in tubes containing Sauton's liquid and could become implanted and develop equally well in the new Löwenstein medium. The tuberculous protogenes, usually weakly or nonpathogenic for guinea-pigs, could develop in the latter medium into typical tuberculiogenic macrocultures or into invisible, nonpathogenic microcultures. The last mentioned are capable, by subculture, of producing macrocultures possessing tuberculiogenic properties. The use of egg nutrient mediums is necessary to obtain cultures of "tuberculous protogenes." Long cultivation in vivo or in vitro progressively weakens the vitality and powers of adaptation and multiplication of the tuberculous protogenes. Among the factors able to impede the development of the protogenes is the weakly bactericidal action exerted by the peritoneal fluid. The progressive diminution of vegetative power of the protogenes occurring in the double collodion sacs lying in Sauton liquid suggests that it is the long absence of air that causes their arrested development. This absence of air has also an unfavorable effect on adult tubercle bacilli. The authors conclude that the technic of double collodion sacs lends itself well to the study of filtrable elements of the tuberculous virus.

- *Histidine in Gastric Therapeutics L Manginelli—p 460

Histidine in Gastric Therapeutics—On the basis of the conception gained largely from animal observations that gastric ulcer is a result of general metabolic disorder due to amino acid (histidine) deficiency, Manginelli treated fifty-one patients with histidine. He used 2 cc. of a 4 per cent solution at a dose. The solution was weakly acid. The injections were usually made intramuscularly, although the intravenous route was also found satisfactory. They were made daily for twenty or thirty consecutive days and, after a brief period of rest, a second series of from fifteen to twenty injections was given. Rarely was a third series employed. When the injections were given intramuscularly the author preferred the hour just before a meal, when intravenously, just after eating. In gastroduodenal ulcers the rapid and intense analgesic effect of histidine was striking. The accessory symptoms also improved: tolerance for food, localized areas of tenderness to pressure and the roentgenologic picture. In gastritis the results were less prompt and constant. Histidine is indicated for the gastric neuroses because of its analgesic effect and of the reestablishment of the vegetative system equilibrium. He concludes that histidine exerts an intense analgesic action on several painful syndromes. In ulcers and some forms of gastritis it has in addition a specific curative action on the final phase of the anatomic process, serving also as a specific reconstructive material. The mechanism of action is probably both plastic and chemical, which accounts for its elective therapeutic effect.

Serum Proteins in Pathologic Pregnancy and Puerperium—Olivetti and Valle state that the content of whole proteins in the blood in normal pregnancy and the puerperium is lower than that in normal conditions, although there is a shift to the left of the albumin-globulin quotient, which is more marked during the puerperium. The variations of proteinemia in either normal or pathologic pregnancy are not related to a dysfunction of the liver, but the hypotheses that hyperglobulemia is a reaction of defense of the pregnant organism against ovarian toxins or a modification of the plasma due to endocrine hyperfunction are not as yet proved. The predominance in the quantity of globulins over that of serum albumins during the first days of the puerperium seems to be due to the greater velocity in regeneration of the former over that of the latter, following considerable or repeated losses of plasma due to the hemorrhage of labor, the elimination of lochia and lactation. Serum proteins follow the same behavior in normal pregnancy and in the various diseases that occasionally complicate it. But the fact that they act differently in the diseases that specifically complicate pregnancy makes the conception of Seitz and Eufinger, that certain toxicoses of pregnancy are due to a dysfunction of the blood colloids and ions, unacceptable. The occasional deviations of the protein formula in the various toxicoses of pregnancy are neither constant nor univocal and are not proportional to the seriousness of the pathologic condition. The determination by the authors of the osmotic pressure by Govaert's formula, in cases of pregnancy edema, showed that there is a relation between the lowering of the osmotic pressure and the retention of the fluids in the tissues. The results indicate that qualitative and quantitative variations of serum proteins are an important factor in the pathogenesis of edema. In puerperal infection there is a lowering of the protein quotient similar to that which is observed in some other infectious diseases. If globulins have mechanical properties for the transportation of immune bodies, as has been hypothetically assumed, the deviation of the protein quotient in puerperal infection should be considered a reaction against the infection.

Casoni's Reaction in Suppurative Echinococcosis—Cortesini calls attention to the importance of a positive Casoni reaction in the diagnosis of suppurative echinococcosis of the liver and of the lung, after removal of an echinococcus cyst from either organ. He reports two cases in which the reaction continued positive after removal of a large nonsuppurative echinococcus cyst of the liver in the first case and of a suppurative echinococcus cyst of the lung in the second. The reaction became negative after a second elimination of the cysts, both suppurative and nonsuppurative, in the two cases. The author explains that the persistence of the positive reaction was caused by antigens in the circulation, originating in the remaining cyst and maintaining the allergy of the patient. The suppuration probably caused leukocytosis and the disappearance of eosinophils in the two instances without interfering with the biologic mechanism of the allergy.

Treatment of Children with Tetanus—Noeggerath, in discussing the prognosis of children with tetanus, points out that formerly it was based, just as in adults on the length of the period of incubation. The shorter incubation periods (up to ten days) were considered as a much more unfavorable sign than the longer incubation periods. In the new-born the limit was set at six days. The author analyzes his own material of fourteen cases and finds that their outcome largely corroborates the former opinion in regard to the unfavorable prognosis of cases in which the incubation period is short. However, he gained the impression that the rapidity of the progress of the disease is likewise an indicator of the outcome. In this connection he calls attention to the five phases that have been differentiated in the course of tetanus. It appears that, if the symptoms of the advanced stage appear soon, the prognosis is unfavorable whereas, if they do not, the prognosis is relatively favorable. In discussing the prospects of the treatment of tetanus in children, the author points out that he saw no noticeable difference in the efficacy of the earlier or later onset of the treatment. The author gives his attention to the causes of death and stresses that the failure of the circulatory and respiratory systems is of great importance. He points out that spasms of the involuntary muscles particularly of those of the respiratory organs, play an important part in tetanus of children. In the treatment of tetanus, attention must be given chiefly to the respiration. The spasms of the respiratory organs must be counteracted by spasmolytic remedies, but the administration of oxygen is likewise important. An oxygen tank should always be in readiness, particularly during the stage of the reflex spasms. It is also important to quiet the patient and to counteract the spasms. In this connection the author evaluates the use of sedatives and hypnotics. The specific treatment of tetanus has two chief aims to render the focus of infection harmless and to neutralize the toxin of tetanus. Not much can be gained by the surgical treatment or cleansing of the infected wound after tetanus has already developed. Opinions are still divided on the second aim of the specific treatment, the neutralization of the tetanus toxin. The author thinks that large doses of the tetanus antitoxin are required.

High Carbohydrate and Low Fat Diet in Diabetes—Krakauer reports his observations on adult patients with diabetes mellitus who were free from coma and from other complications. He commences the treatment by completely stopping the old diet and putting the patient on a milk diet for from one to three days. After the milk days he gives a mixed diet if possible without insulin. Carbohydrates are added to the diet in proportion to the increasing tolerance. The fat intake is restricted so as to avoid acidosis. Protein is given in quantities of 1 Gm. or slightly more for each kilogram of body weight. The diet is varied and takes into account the desires and requirements of the patients. The calories are reduced to a minimum. This type of dietetic treatment produced better results than the diet providing large quantities of fat formerly employed by the author. The new diet proved especially helpful in patients with persistent hyper-

glycemia and acetonuria. In general, this diet produced a higher carbohydrate tolerance and made possible the intake of a larger number of calories when it was completed. In 83 per cent of the patients, sugar as well as ketone disappeared from the urine. The blood sugar became normal in 25 per cent. In 23 per cent, insulin treatment had to be continued. The patients liked the diet, for it satisfies, adjustment to it is effected quickly and it can soon be complemented, so that it can serve as a satisfactory permanent diet.

Local Hyperplasia of Fat Tissue Following Insulin Injections—Adlersberg observed in a woman, aged 20, who had had diabetes since her 14th year, soft, cushion-like, symmetrical swellings, about the size of a fist on the lateral portion in the lower third of the upper arms and on the thighs. The skin over these swellings can be moved readily and there is no sensitivity to pressure. Palpation reveals that the fat tissues at these sites are from two to three times the normal thickness. These lipomatous formations are at the sites used by the patient for the insulin injections. In the course of three years the patient was repeatedly advised to avoid injections into the one or the other of these lipomatous formations. When injections into a certain swelling were avoided for two or three months there was only a slight reduction in their size, never a complete disappearance. At first it was considered possible that the procaine hydrochloride which the patient added to the insulin might be a cause of the fat hypertrophy. This was considered the more likely since procaine hydrochloride exerts a favorable influence on the atrophy of the fat tissue that has been observed in some diabetic patients at the site of the insulin injection. That this assumption was erroneous was proved by the fact that for several years the patient had added procaine hydrochloride only to the insulin that she injected into the arms but not to that which she injected into the thighs, justifying this by asserting that the skin of her arms is more sensitive than that of the thighs, yet the swellings on arms and thighs were of about the same size. The assumption that traumatic influences might be responsible could not be corroborated, and the author concludes that the lipomatous swellings are due to the insulin injections as such. A careful search for similar cases among the large diabetic material of the author's clinic disclosed one other case concerning a man, aged 21. The author thinks that this disorder affects chiefly young persons, and he assumes that, like the insulinogenic atrophy of the fat tissue, this hypertrophy is largely the result of a predisposition. He thinks that the disorder might be prevented by using for the injection as many different sites as possible.

Roentgen Therapy in Metrorrhagias During Menopause—Bécère discusses the indications for roentgen therapy in the metrorrhagias that develop during the menopausal age. He emphasizes the importance of an etiologic diagnosis, in order to discover the patients who have objective pathologic changes in the uterus or in the oviducts. He thinks that such changes can be found in about 30 per cent of the patients. Especial efforts must be made to detect the cases of cancer of the uterus, which amount to about 8 per cent of the total. The objective pathologic changes can usually be determined

by means of hysterosalpingography following the intra-uterine injection of iodized poppy-seed oil. Moreover, hystero-graphy is helpful in guiding the biopsy. Biopsy and histologic examination are necessary in order to arrive at a definite diagnosis of cancer of the uterus. In about 70 per cent of the women who have metrorrhagia during the menopausal period, hystero-graphy or histologic examination shows that the hemorrhages are of purely functional, usually ovarian, origin. In such cases roentgen therapy is helpful. The author recommends one irradiation each week and suggests that the doses be applied in such a manner that the total dose necessary for castration is given in eight sessions, that is, the treatment is distributed over a period of two months.

*New Technic of Fuchs' Reaction for Diagnosis of Cancer H. Minibek—p. 362

New Technic of Fuchs' Cancer Reaction.—Minibek points out that Fuchs' cancer reaction is too difficult to be performed in the average laboratory. He therefore devised a new technic which is based on a titration of the amino groups and which indicates differences of 0.23 mg. per hundred cubic centimeters. He determines the amino nitrogen value of the serum (1) without any addition, (2) following the addition of normal fibrin and (3) after the addition of carcinoma fibrin. He compared his technic with other methods of determination of the amino acids and found that his titration is well suited for a carcinoma reaction because it also determines the peptides and other cleavage products and because it is simple. In seventeen patients with carcinoma the outcome of his titration method tallied with the clinical diagnosis as was the case also in twenty-three patients without carcinoma. In six cases the outcome of the test was doubtful. The determination of the amino acids according to Folin and Wu makes it possible, particularly in the cerebrospinal fluid, and, if larger quantities of cleavage products are present, to prove the presence of new amino groups in a parallel test to the titration. Without hydrolytic cleavage this colorimetrically determinable increase is only slight. A hydrolysis, as it is required for the determination of the peptides by the colorimetric method, is unnecessary in titration. The cleavage products cause from 10 to 60 per cent increase in the titrable amino nitrogen. These great fluctuations facilitate the estimation of the reaction.

Stage Preceding and Course of Early Pulmonary Infiltrate.—Rehberg points out that the opinions about the mode of development of the early infiltrate are still divided. He stresses that, in view of the deficiency of symptoms, roentgenologic examination is highly important during this period. He describes a case of early infiltrate in which the patient was under roentgenologic control from the time when the lung was still without a focus until five weeks later, when the infiltrate had already undergone cavernous disintegration. Then he describes another case in which the early infiltrate, the cavern as well as the dissemination, disappeared rapidly.

Nondetached Pleural Strands in Pneumothorax Treatment.—Jüttemann illustrates the danger presented by pleural strands first on the basis of an extreme case of so-called hang-

ing cavern. Then he describes a number of cases in which the success of the pneumothorax therapy persisted for some time but in the end proved nevertheless to be only an apparent success. He shows that the failure of the pneumothorax treatment in these and similar cases is due to the persistence of pleural strands. He discusses how pleural strands may become harmful during the different phases of pneumothorax therapy and how they may prevent a permanent success of the treatment in spite of a good result in the beginning.

Indophenol Blue-Oxygen Reaction of Blood in Cancer of Uterus.—Michaelis determined the molecular oxygen in the venous blood of cancer patients. The venous blood is with drawn and prepared under the exclusion of oxygen. In a mixture of dimethylparaphenylenediamine base and alpha naphthol with the addition of a 5 per cent solution of ammonia the envelopes of the erythrocytes are destroyed and the molecular oxygen is liberated. During this process indophenol blue develops. After a certain time the quantity of indophenol blue is determined in the colorimeter that employs the monochromatic sodium light and is equipped with a millimeter scale. This determination is likewise made under the exclusion of oxygen. The author concedes that the quantity of molecular oxygen (that is, the indophenol blue value) has a definite relation to the hemoglobin content, for a person who has a hemoglobin value of only 50 per cent has, of course a lower indophenol blue value than a person who has a hemoglobin content of 80 per cent. For this reason it is necessary to determine the hemoglobin content of the blood and to compare it with the indophenol blue value. The author found that, whereas in normal women a hemoglobin value of 70 per cent corresponds to an indophenol blue value of from 40 to 44.5 mm. on the colorimeter scale, in women with cancer a hemoglobin value of 70 per cent corresponds to indophenol blue values of from 48 to 55 mm. The higher indophenol blue value indicates thus the presence of cancer. The author shows tabular reports that bear this out. The correctly recognized positive cases (verified by histologic examination) amounted to 83 per cent. Tests on persons who were free from cancer gave positive results in 10 per cent, but in all other persons who were free from cancer the reaction was negative. In attempts to improve the indophenol blue-oxygen reaction, attention was given to the frequently increased sugar content of the blood of cancer patients and to the substances resembling fatty acid contained in it. The modified indophenol blue method overcomes these disturbing factors by preceding the blood withdrawal from the fasting patient by an administration of 20 units of insulin (two hours before) and by washing the blood with ether.

*Atrioventricular Block. Peculiar Case W. T. Andersen—p. 524

Pellagra Three Cases A. Nyfeldt—p. 529

Atrioventricular Block.—In a boy, aged 15, the electrocardiogram showed complete block. After rest in bed for five months the condition was apparently unchanged. There is no history of any infection. The entire course, Andersen says, testifies against rheumatic block. Coronary sclerosis is excluded. The condition is attributed to a congenital malformation not manifested until now, the anomaly has caused an aortic and a mitral insufficiency and interrupted the connection between atria and ventricles. Because of the disorder of the valves the prognosis is grave.

SOME ROENTGENOLOGIC STUDIES OF THE DYNAMICS OF THE THORAX

CHAIRMAN'S ADDRESS

J W PIERSON, M D
BALTIMORE

A knowledge of the dynamics of the thorax is important not only from the standpoint of diagnosis but also for the aid it affords in evolving new therapeutic procedures. The activities of the physical agents that participate in respiration are well understood and the changes that result from suppression or abolition of one or more of these activities have furnished a fertile field for investigation. The most potent force acting within the thorax is the negative intrathoracic pressure. It is absolutely essential to the normal expansion of the lungs and, if it is not maintained, diminished lung capacity must ensue. Another important factor is the elasticity of the lungs, which, acting in conjunction with the negative intrathoracic pressure, serves to keep the thorax filled. This is true in the presence of abnormal as well as of normal conditions. Whenever diminished lung volume occurs; the compensatory mechanism of the chest, acting chiefly through the negative intrathoracic pressure, seeks to establish an equilibrium by reducing the size of the thorax and causing dilatation of the normal lung tissue. The compensatory dilatation of the lungs becomes progressively greater the longer the abnormal condition persists, until finally it causes the normal lung to become large enough to restore the original size of the thorax. This mechanism works in exactly the same way in all cases of diminished lung capacity from whatever cause, whether congenital absence, atelectasis, or surgical removal of a lung.

Cases of congenital absence of one lung furnish noteworthy examples of the compensatory mechanism of the thorax acting at its maximum capacity. Most of these patients succumb early, chiefly because of the effects of other abnormalities, but reports indicate that some do reach adult life and attain a normal physical development. The single lung of these individuals becomes enormously enlarged and apparently functions effectively, as the patients have led normal active lives and have displayed no embarrassment to the functions of respiration. The following case is an excellent example of the manner in which a single lung will dilate and fill the entire thorax.

C. C. was an infant who was born with many abnormalities including absence of one lung, deformities of the spine and ribs, and aberrations in the development of the intestinal tract. He finally succumbed to the latter. Roentgen examinations revealed that the right lung completely filled both sides of the thoracic cavity and that the heart occupied such a position that its out-

line was not silhouetted on the film. Postmortem examination demonstrated that there was complete absence of the left lung and that the entire thorax was filled with the right lung. The heart was displaced to the left and rotated posteriorly. The great increase in the size of the lung was accomplished solely by dilatation and not by proliferation of lung tissue. Heuer and Ruenhoff have definitely proved this point by animal experimentation.

Complete atelectasis of an entire lung produces essentially the same conditions as if the lung were absent. In the following two cases of traumatic atelectasis, injury fortunately occurred when the patients were quite young, a time that is ideal for the functioning of the compensatory processes of the chest.

A white man, aged 28, was easily fatigued, complained of an occasional precordial pain of two months' duration, was troubled with a slightly productive cough, had dyspnea on exertion, noticed slight palpitation, and had lost 12 pounds (54 Kg). The family history was not important. He had been run over by an automobile at the age of 9 without any fractures, but he did cough up a little blood for a short while afterward. Tonsils and adenoids had been removed at the age of 16, with uneventful recovery. The past history was otherwise negative.

Physical examination revealed chest expansion on the left side distinctly limited as compared with the right. The left supraclavicular fossa was deeper than the right. The percussion note was everywhere resonant and natural except at the left base. Breath sounds on both sides were natural. No rales were detected even after coughing. There was a well marked systolic impulse at the left base posteriorly, with flatness over the entire left lower lobe. The heart sounds were heard clearly at the left base posteriorly but were loudest in the left mid-axilla. Otherwise the physical examination was negative.

Roentgen examination on admission showed that the left side of the thorax was contracted and that the heart, trachea and great vessels were displaced to the left. The lower portion of the left lung field was clouded and the shadow of the diaphragm obliterated. The right lung field was clear. The lateral view showed that the heart was rotated posteriorly, causing a great increase in all dimensions of the anterior mediastinum. This lateral shifting and posterior rotation of the heart constitute a characteristic sign, which appears whenever the left lung is either greatly reduced in size or entirely absent.

The clinical impression was that there were pleuropericardial and pleurodiaphragmatic adhesions.

Operative intervention for the release of the adhesions was decided on as the proper method of treatment.

Preoperative pneumothorax was done in several stages over a period of a month, with expectoration of small amounts of blood in the same afternoon after the fourth stage, prior to which there was thought to have been more than 50 per cent collapse of the left lung.

Roentgen examination after repeated introduction of air into the left side of the thorax disclosed that the heart, trachea and great vessels had resumed their normal positions, that the contour of the left side of the cardiac shadow was very unusual and that the left side of the diaphragm was not clearly demonstrated. The lateral view showed that the cardiac shadow still lay in a position that was more posterior than normal and that a conical shadow was superimposed on the cardiac shadow, which in the light of later developments, could evidently have been interpreted as collapsed and atelectatic left lung. The

return of the heart and great vessels to their normal positions following pneumothorax was no doubt the result of the positive pressure within the left side of the thorax.

When the thorax was opened, the main bronchus was found to be occluded, the left lung was but a small fraction of its normal size, and it was of the consistency of rubber. Adhesions extended from both the upper and lower borders of the pericardium to the chest wall, from the anterior surface of the lung to the pericardium, and from the lower pole of the pericardium to the diaphragm. The entire aorta was found to be mobile after the adhesions had been cut, and a space about 6 inches long was seen between the sternum and the conus. This space was filled with pleura, but it provided free communication between the two sides of the thorax, as shown by the fact that the pleura was seen to bulge through the space and into the left thoracic cavity on reinflation of the right lung. The left lung did not reinflate but seemed solid, and a piece of it was removed for study.

The operation showed complete atelectasis of the left lung, with rotation and posterior displacement of the heart. The conjecture was made that a portion of the right lung had extended into and almost completely filled the left side of the thorax. Pathologic examination revealed atelectatic lung tissue.

Roentgen examination made the day after the operation showed that a most pronounced change had taken place in the positions of the thoracic organs. The right lung was now partially collapsed and the heart, instead of lying in the left thoracic cavity, now lay wholly within the right. This sudden postoperative shifting of the heart from the left side to the right was due primarily to the large opening in the mediastinum which permitted the positive pressure in the left side of the thorax to exert an unusual amount of force on the right lung. The presence of atmospheric pressure in the left side of the thorax was, of course the result of surgical invasion of that side. The portion of the right lung that presented through the opening of the mediastinum was covered by three layers of pleura, its own visceral and parietal and the left parietal. These three layers of pleura must have remained intact, because the x-ray film made on the following day revealed the astonishing fact that the heart had returned to the left side. The left thoracic cavity must by this time have become sealed and the atmospheric pressure reduced to zero, or else the right lung could not have expanded and displaced the heart to the left. This case, in which the heart occupied preoperatively the left side of the thorax and the first day after operation the right and finally the next day returned to the left side, serves to demonstrate the swiftness with which changes in the intrathoracic pressure act to produce dislocations of the thoracic organs.

The postoperative course was relatively calm with occasional thoracenteses. After the patient's temperature had been down for several days he was discharged, the thirty-fourth day after operation. Eight months following operation, injection of iodized oil demonstrated that the obstruction to the left bronchus persisted and that the right lung filled the entire right side of the chest and the major portion of the left.

In the second case both the clinical manifestations and the results of the roentgen examination were so similar to the previous case that a diagnosis of atelectasis of the left lung and overexpansion of the right lung was made. Demonstration of the bronchi by means of contrast mediums revealed obstruction to the left bronchus and occupation of both sides of the thoracic cavity by the right lung.

The two outstanding features of these cases were the great size attained by the right lung and the ease with which it traversed the mediastinum. This was demonstrated both at operation and later by bronchography. These cases of traumatic atelectasis of one lung are examples of true herniation of the lung and are not to be confused with the herniations that are sometimes produced in cases of therapeutic pneumothorax. The physical effects in the latter group of cases are just the opposite of those under consideration and are the result of high positive pressure on the side on which the pneumothorax has been induced.

The observations made in these cases were of further interest because they established the soundness of Rienhoff's theories regarding thoracic surgery. The technic employed by him produced exactly the same set of physical conditions as in the cases that have been just described. He abandoned all attempts to reduce the size of the thorax following the removal of all or part of a lung. Instead he preserved the thorax intact and depended on the normal lung to expand and occupy the space left vacant by the portion that had been removed.

Rienhoff employed this technic in a patient $3\frac{1}{2}$ years of age. The left lung was removed because of a tumor that obliterated the main bronchus. The thoracic cage was kept intact and the thorax was closed, leaving a large cavity in the left side. Four days after operation both the physical signs and the x-ray films indicated the presence of fluid in the left thoracic cavity together with immobility of the left side of the diaphragm and displacement of the heart to the right. Later films disclosed gradual absorption of the fluid and development of dense bands of pleural adhesions, which formed pockets for the retention of the fluid. At the end of three weeks the heart had returned to the left of the sternum and it was evident that the right lung had expanded and occupied a portion of the left thoracic cavity. This process continued until the right lung had expanded to such a size as to cause displacement of the trachea and heart to the left and obliteration of the major portion of the vacant space in the left thoracic cavity. This was vividly demonstrated on x-ray films ten months later, with the assistance of the intratracheal injection of iodized oil. As soon as the left side of the thorax had become filled with the right lung, the fluoroscopic examination revealed that the diaphragm and intercostal muscles had almost completely resumed their normal function. The same condition existed at the end of twenty months.

The same type of operation was performed on a patient, aged 23 years, whose left lung was removed for a tumor that occluded the bronchi of the lower lobe. Four days after operation, signs of fluid appeared and 100 cc of fluid and 500 cc of air were removed by thoracentesis, changing a well marked positive into an equally well marked negative intrathoracic pressure. Small amounts of fluid were withdrawn from time to time, but the negative intrathoracic pressure did not persist as at the end of three weeks x-ray films revealed a pocket containing free air and communicating with the bronchus. The left side of the thorax, because it was not occupied by expanded lung, was gradually diminished in size, the ribs did not move on inspiration and the diaphragm was fixed. At the end of nine months the right lung was greatly increased in size in all dimensions and the vital capacity of the patient was approximately two-thirds that of normal. The persistence of the bronchial fistula maintained a mild positive pressure in the left side of the thorax, which prevented the right lung from entering it.

Different results were obtained in these two cases because a different set of physical factors prevailed. In the first the compensatory mechanism of the thorax functioned perfectly and complete restitution was obtained because the negative intrathoracic pressure was restored in the side from which the lung had been removed and the mediastinum was patent. In the second, the persistence of the bronchial fistula prevented the restoration of the negative intrathoracic pressure on the left side, thereby preventing the right lung from entering the left thoracic cavity. The persistence of the

cavity in the left side of the thorax has not so far caused any difficulty. The cavity is gradually diminishing in size and the roentgen examination at the end of nineteen months reveals that it is approximately one-third as large as it was immediately after the operation.

Consideration of these three groups of cases shows that the same compensatory mechanism functions in the presence of diminished lung size, no matter what the primary cause. Several essentials are necessary in order to permit of the proper functioning of the processes of restitution. First, the lung must be capable of expansion. Certainly an overexpanded emphysematous lung is not able to respond to the influence of a negative intrathoracic pressure as readily as a lung in which the normal elasticity has been preserved. Second, the mediastinum must be patent. This factor is governed very largely, though not wholly, by the age of the patient. The reason for this is quite obvious, because advancing age causes fixation of the mediastinal structures. Infection in operative cases plays an important role in a negative sense. If present it also causes fixation of the mediastinum and it renders the permanent closure of the bronchus more difficult.

The results obtained in the operative cases would seem to justify the technic, which is designed to utilize the compensatory mechanism of the thorax. Furthermore, preservation of the thoracic cage provides protection for underlying structures, aids in early restoration of the normal physiologic functioning of the thorax, and avoids the necessity of a deforming operation.

FACIAL ERYSIPELAS

EVALUATION AND COMPARISON OF SPECIFIC ANTISERUM AND ULTRAVIOLET THERAPY

H. JERRY LAVENDER, M.D.

AND

LEON GOLDMAN, M.D.
CINCINNATI

Many years ago one of us¹ lauded the merits and superiority of antistreptococcus serum over many other methods in the treatment of facial erysipelas. Shortly after this the specific antiserum came into use and replaced to a great extent the antistreptococcus serum.² Although the advocated use of ultraviolet rays as a treatment of erysipelas is not new,³ it was only after the work of Ude⁴ and Titus⁵ that much attention was drawn to this form of treatment and the efficacy of the ultraviolet rays was evaluated. The work reported here was completed in order to compare our results with those of other investigators, to draw conclusions and to mention some points in the comparison that may be not only pertinent but interesting as well.

It is important to note that only adult facial erysipelas, in which no operation had been done and which were seen during the seasons 1933-1935 inclusive, were considered in this study.

From the Department of Dermatology, Cincinnati General Hospital, service of Dr. Elmore B. Tauber.

⁵ Titus, N. E. Erysipelas—Treatment with Ultraviolet Light. Arch. Phys. Therapy 14: 22 (Dec.) 1933.

In all, ninety cases were studied. Of these, seventy patients were white, sixty-three were males, and the ages ranged from 18 to 78 years. The ninety cases were subdivided as follows: thirty-two cases in which the specific antiserum alone was used, twenty-six cases in which ultraviolet therapy alone was used and thirty-two cases which were used as controls with no therapy.

Chart 1—Febrile period. Solid line indicates serum, broken line indicates ultraviolet therapy, circles Burrow's solution.

other than continuous wet applications of diluted Burrow's solution.

No case in which a combination of these treatments had been used was considered in this series. Alkalinization and complete bed rest during the febrile period were carried out in all cases. The total lapse of time after onset, before treatment was instituted, gave a total average of 2.4 days, with 2.5, 2 and 2.8 days for the serum, light and control cases, respectively.

This factor is important for, especially in general hospital practice, patients are not seen immediately at the onset of their infection. Naturally, this information was obtained usually from the patient's history. These data, as a rule, have not been mentioned specifically in many of the previous articles on erysipelas. The fever peak (before therapy) gave a total average of 103.3 F, with 103.7, 103.8 and 102.6 F, respectively, for the serum, light and control cases. In forty-five cases, or 50 per cent of the whole series, the entire face was involved at the time of the onset of treatment, and there was a general average in the white blood count of 14,000 cells.

In the serum series (thirty-two cases) the same make of a standard and uniform preparation of specific serums was used throughout. All injections were

TABLE 1—Comparison of Hospital Febrile Periods in Control Cases of Various Investigators

Ude	151	6.15
Titus	20	6.85
Rosenbaum and Kazzelson	22	8.50
Lavender and Goldman	32	3.90

made intramuscularly and at twenty-four hour intervals. The white count gave a mean value of 15,000. An average of 4.8 injections per patient was administered. The febrile period gave an average of 6.6 days. An interesting observation was made between this febrile period (6.6 days) for intramuscular injections of the serum in comparison with the series in 1924, with 3.9 days (early cases) and 5.4 days (entire series), following antistreptococcus serum when given intravenously.

In the ultraviolet series (twenty-six cases), quartz mercury burners of a standard make were employed.

Tests were made several times weekly to determine as closely as possible the factors governing the erythema dose of the burners. The white blood count gave the same average (15,000) as the serum cases. These patients received an average of three exposures (given approximately twenty-four hours apart) to and slightly beyond the involved area or areas, each area receiving a total of fifty-seven erythema doses, or an average of 188 erythema doses per treatment.

The vast majority of the patients showed a decided improvement within twenty-four hours after the first exposure. Inflammation was lessened, edema was reduced, and areas appeared darker in color and were much drier where excessive vesiculation had been manifested previously. There was at the same time a reduction in fever, in most cases a drop of from 2 to 3 degrees, accompanied by an improvement in the general condition. In fact, it was interesting to note the relative absence of pain or any marked discomfort following the exposure to ultraviolet rays.

If the temperature remained down, no further ultraviolet therapy was administered. If no appreciable drop was noted in twenty-four hours, or if the temperature again began to rise, a second treatment was instituted, and so on. Our patients with an initial average fever of 103.7 F had a febrile course, averaging 4.9 days, in comparison with those of the serum patients with 6.6 days (chart 1).

It should be pointed out, however, that the ultraviolet cases were treated on the average of twelve hours earlier than those of the serum series (chart 2). It was only after the patient remained afebrile for at least twenty-four hours that a 5 per cent ointment of boric acid was applied to the treated areas in order to soften them and to hold the scaling and crusting to a minimum.

One hundred and thirteen cases of Ude and his associates,⁶ treated with ultraviolet rays, required, on an average, 3.8 days to reach normal temperature, and eighteen cases of Titus⁵ required 4.83 days till the temperature became normal, both of these indicating the duration of the hospital febrile period.

The control series (thirty-two cases), as stated previously, was treated only with a uniform strength, approximately 1,000 aluminum acetate (diluted Burow's solution), in the form of continuous wet dressings. We were surprised to learn that the febrile period averaged only 3.9 days, a difference of almost three days shorter than the serum-treated cases and one day shorter than those treated with ultraviolet rays.

Febrile periods in control cases varied from 8.5 days⁶ to 6.15 days in Ude's 151 cases.⁴ Such similar wide variations were reported even earlier, such as eight days in the series of Lenhartz (1902)⁷ and four days of the cases of Pontano (1912)⁷ (tables 1 and 2).

When we began to investigate and to determine, if possible, the reason for the great difference in our own series, we found that twenty-three of our control cases were admitted and treated in the spring and early summer (from March to June inclusive) while the

vast majority of both the serum and the ultraviolet-treated cases were seen in the fall and winter months (chart 3). It was also noted that the control cases gave only a 12,000 white count average against 15,000 each for the other series and had an average initial peak of only 102.6 F, and, which was even more striking, that ten of the control cases originated in the same lodging structure, an old building for housing persons then under the Federal Relief Administration.

Our control series, therefore, was not a fair and just comparison, since seasonal influence and common source of infection had played a large role in our

Chart 3—Seasonal incidence. Percentage of cases. Solid line indicates serum, broken line ultraviolet therapy, circles Burow's solution, crosses entire series.

comparative investigation. One should not make comparisons on the length of stay in the hospital, since so many factors play a role in these determinations that it makes the conclusions inaccurate and, indeed, in many respects, puts them on a false basis.

Of the complications in the serum series, there were seven cases of serum sickness, one necrosis of the lids, one abscess of the scalp, two toxic arthritides and one alopecia of the scalp, in the ultraviolet series one toxic psychosis, one polyarthritis, one otitis media and two abscesses of the scalp, in the control series, one bilateral external otitis.

Of our total series of ninety cases, it was interesting to note that only five gave a history of previous attacks of erysipelas, these with an average of two attacks.

TABLE 2—Comparison of Hospital Febrile Periods in Cases Treated with Ultraviolet Rays by Various Investigators

Authors	Number of Cases	Days of Fever
Ude	113	3.80
Titus	18	4.83
Lavender and Goldman	26	4.90

There were seven deaths in our total series, or about 6 per cent. Of these, six deaths occurred in the control series. The causes of death were listed as:

- 1 Coronary thrombosis
- 2 Streptococcal septicemia and diabetic coma, postmortem.
- 3 Arteriosclerotic hypertensive heart disease with congestive failure.
- 4 Diabetic coma
- 5 Lobular pneumonia, obliterative pericarditis, postmortem.
- 6 Rupture of aortic aneurysm, postmortem done
- 7 Peritonitis, probably streptococcal.

Blood cultures were obtained in all these cases and were positive ante mortem only in the case of streptococcal septicemia.

It must be emphasized that there are many variables in making comparisons of any nature, and especially is this true of the treatment of facial erysipelas.

Chart 2—Comparison of febrile periods with time of onset of therapy. Solid line indicates serum, broken line, ultraviolet therapy, circles, Burow's solution.

⁶ Rosenbaum M and Karselson R. Gegenwärtige Erysipelbehandlung. *Wien klin Wchnschr* 42: 1534 (Nov 28) 1929.
⁷ Cited by Tuleston.

The seasonal incidence, the lapse of time before the onset of treatment, the general condition or debilitation of the patient and previous treatment are just a few of the matters that play a marked role in the evaluation of the therapy instituted

We believe that, if all these factors are considered, one should not be so confused in evaluating the effect of various types of therapy, and, therefore, we do not agree with the statement that "the duration of the disease is so variable that it is very hard to judge the effects of therapy"⁸

That ultraviolet therapy is equal if not superior to serum therapy is, we feel, very evident. Aside from the economic issue, which is an important one (cost of serums), the end results, governed by the quicker response to treatment and the fewer complications, make ultraviolet therapy for facial erysipelas quite distinctive, and, indeed, the method of choice

CONCLUSIONS

1 In all, ninety cases of adult facial erysipelas were observed from 1933 through the spring of 1935

2 Thirty-two of these cases were treated with specific antiserums with an average of 48 injections

3 Twenty-six patients were given intensive ultraviolet therapy with an average of 188 erythema doses at a treatment and an average of three treatments for each patient

4 Thirty-two cases were used as controls with simple wet dressings

5 A critical analysis of the data showed ultraviolet rays to be the therapy preferred

HEMATURIA AS A COMPLICATION OF PREGNANCY

HAROLD L. MORRIS, MD

DETROIT

Hematuria as a symptom of the presence of pathologic changes in the urinary tract is well known, and, from the urologic point of view, has had a rather comprehensive study, especially in the past few years, in respect both to systemic disease and to lesions within the urinary tract proper. As a result of these studies the term "essential hematuria" is seldom used, and when used it is applied only to those cases in which a painstaking medical and urologic investigation has not revealed the etiologic factor or factors causing the hematuria

Stevens⁴ states that "the causes, medical and surgical, of blood in the urine are so manifold that the more one studies the subject the more one is inclined to the belief that a thorough understanding of hematuria means a comprehensive knowledge of diseases of the whole body"

While this is a rather ambitious statement, nevertheless the importance of hematuria as an indication of grave renal disorder cannot be too strongly emphasized. Concerning hematuria as a symptom of systemic disease, Locke and Minot² say "Although patients with hematuria dependent on diseases other than those of

the urogenital tract form but a small minority of all, they are, nevertheless, important and will explain at least some of the cases heretofore called essential hematuria"

The systemic conditions in which hematuria may arise comprise a relatively large number of morbid states, which have been grouped thus (1) diseases and conditions of the hematopoietic system, (2) diseases and conditions resembling those associated with pathologic conditions of the blood, (3) infections, (4) conditions causing chronic passive congestion of the kidneys, (5) toxic agents and (6) miscellaneous conditions

In all instances of blood in the urine, the lesions to be looked for in the urinary tract may occur anywhere from the external urethral orifice to the renal capsule, and their presence must be either proved or disproved. The conditions in the genito-urinary tract which the urologist must exclude by his examination are

1 Congenital defects and anomalies of the upper urinary tract, including polycystic disease.

2 New growth, benign and malignant, of the urethra, prostate, bladder, ureters, renal pelves, and kidneys

3 Foreign bodies anywhere in the urinary tract

4 Trauma, either instrumental or from direct violence

5 As a result of chemicals either by direct application or by drugs given

6 Mechanical defects as a result of abnormal motility, this being the primary factor in stasis and infection in localized areas of the urinary tract

7 Infections, acute and chronic.

In many instances there is a combination of two or more of these factors present in a single case, as well as the presence of a systemic disease

The literature is replete with works dealing with hematuria, but the infrequency with which hematuria in pregnancy has been dealt is noteworthy, since the number of pregnancies complicated by hematuria is by no means small. Out of the total of 154 consecutive pregnancies seen by me for urologic consultations, thirty, or about 20 per cent of them, were complicated by hematuria. The dearth of material in the literature regarding the presence of hematuria during pregnancy led me to review the pregnancies referred to my service at the Womans Hospital with urinary tract complications. A brief review of the literature to date follows.

Becker³ finds hematuria an important symptom because of its early appearance in the toxemias of pregnancy. When one realizes that 100,000 women in the United States have pregnancies complicated by toxemia and that many of these toxemic women are partly incapacitated or that their life expectation has been definitely shortened because of irreparable injury to the kidneys, vascular system or heart, its importance is readily appreciated

In 1921 Dattin⁴ reviewed the literature from 1843 to 1921 on the subject of hematuria occurring in the course of pregnancy. Some twenty cases had been reported during that period. None of them were properly investigated according to present urologic standards, and it is impossible to evaluate them.

Dattin presented nine cases of his own. In only four of these cases was cystoscopy performed. Pyelograms were not made in any of them. The hematuria was ascribed to such causes as cystitis following retention in two cases, congestion of the mucous membrane of the bladder with rupture of veins of the mucosa,

ptosis of the kidney with hydronephrosis, and varicose veins in the bladder in two cases. In three cases no cause for the hematuria was discovered.

Kirkwood⁶ reports a case in which hematuria appeared in the ninth month of pregnancy. The hematuria continued until ten days post partum. Delivery was normal. In this case symptoms of toxemia did not appear until the patient was very nearly at term. Too frequently, however, the hematuria occurs in the fourth or fifth month and is disregarded until toxemia is well advanced, the end result being death to either the mother or the baby or both.

Two cases are reported by Bugbee.⁶ One in which there was a profuse hematuria localized as unilateral, occurring in a woman five months pregnant, was not relieved by pelvic lavage but ceased two weeks after the uterus was emptied. Another case of hematuria, the source of bleeding being the left kidney, came under observation when the patient was two months pregnant. Complete urologic examination showed deficient function of this kidney but no evidence of infection. The patient had a positive Wassermann reaction. The bleeding ceased after the administration of arsphenamine.

Quigley⁷ cites a case of which he says: "Of the various causes offered for hematuria, and for hematuria in pregnancy in particular, it seems to me that the most plausible etiologic factor in this case was toxemia, as evidenced by increased blood pressure and edema."

Bazan⁸ reports the case of a woman, aged 38, in her third pregnancy, who had right renal pain, hematuria, pyuria, and staphylococci in the urine. Repeated cystoscopies did not reveal the source of the hematuria. Roentgenograms were negative for calculi, and no tubercle bacilli were found.

Livermore⁹ presents another interesting case, showing evidence of bilateral pelvic infection and hematuria at the sixth month of pregnancy. The hematuria ceased after bilateral pelvic lavage with 5 per cent silver nitrate.

Perez¹⁰ reported a case in which a woman, aged 27, had hematuria from the sixth month during her eighth pregnancy, in which was demonstrated a *Bacillus coli* right pyelitis. He considered this case an example of essential hematuria. No pyelograms were made.

Reist¹¹ concluded, after a study of eighty patients, in whom the hematuria was present in forty-four cases ante partum and thirty-six cases post partum, that the hematuria was the result of contusion of the soft parts by crushing between the osseous birth tract and the fetus. These conclusions were based on cystoscopic observation of the bladder mucosa, in which he found various types of ulcerations and areas of necrosis in the fundus, trigon and anterior wall of the bladder. No study of the higher urinary tract was made from a bacteriologic or roentgenologic point of view.

Bazan¹² found an abundant hematuria in a woman, aged 42, in the third month of her eighth pregnancy. Cystoscopy revealed some vesical varices and congestion

of the right ureteral orifice. The source of the hematuria was the right kidney. The treatment consisted of pelvic lavage and administration of calcium chloride. The cultures were negative, and no pyelograms were made.

Swanson¹³ reported a case of hematuria of pregnancy occurring in the fifth and sixth pregnancies of a woman, aged 33, at the time of the last pregnancy. The hematuria was accompanied by intermittent attacks of pain in the right renal region. Cystoscopy revealed bloody urine coming from the right ureter. Pyelograms showed right-sided hydronephrosis. No treatment was instituted. The hematuria ceased spontaneously two weeks before delivery in the fifth pregnancy and eighteen days post partum in the sixth pregnancy.

Bolaffio¹⁴ reported two cases of severe hematuria occurring in two patients, one aged 30, during her fifth pregnancy, and one, aged 22, a primipara. Both patients had pyelitis, one on the right side and one on the left side, accompanied by elevation of temperature and corresponding renal tenderness and pyuria. The first patient was given methenamine and anhydrous methylene citrate with methenamine in equal parts in doses of 3 Gm daily. Five days later there was a microscopic hematuria, and seven days after starting the drug there was an abundant hematuria with severe abdominal pain. This required morphine and atropine on the twelfth day. Twenty-four hours later uterine contractions were noted and a stillbirth occurred. The patient was greatly agitated during the day and that night was found dead.

Autopsy revealed "a hyperemia of the meninges, cerebral congestion, hyperemia and chronic inflammatory infiltration of the myocardium, siderosis of the liver, and especially a complex renal lesion of the kidneys and urinary pathways."

"Examination of the kidneys showed a suppurative nephritis with small cortical foci (hematogenous) of recent chronic nature and marked regressive alterations in the parenchyma. The congestion and hemorrhagic infiltration was especially intense in the medullary portion. Congestion and hemorrhagic infiltration was encountered also in the interstitial and subserous parts of the ureters, while a slightly acute inflammatory infiltration was noted in the mucosa. The congestion and hemorrhagic infiltration had involved also the base of the bladder."

"The postmortem examination of the fetus did not reveal anything special outside of those causes inducing fetal asphyxia, although the picture was characterized by an unusual hyperemia and hemorrhagic suffusion of the meninges and kidneys."

The second case ran essentially the same course. The patient was given methenamine and anhydrous methylene citrate with methenamine, and a severe hematuria developed, but because of the sad termination in the first case this pregnancy was interrupted. A live baby was obtained, and the mother was discharged in good condition. In neither case was a urologic study of the higher urinary tract made.

Three cases of hematuria occurring in pregnancy are reported by Albanese.¹⁵ The first patient, aged 39, had suffered from attacks of renal colic, which radiated into the iliac fossae, since she was 16. She never noted blood in the urine. She had had four previous preg-

nancies, and the last two had been complicated by nephritis. In the fourth month of the fifth pregnancy pain developed in both renal regions, diminution of sight, and edema of the face and legs. The urine was bloody for fifteen days previous to examination. The blood pressure was 250 systolic, 170 diastolic. Urinalysis showed numerous red blood cells, and some leukocytes and casts. The case was diagnosed as hemorrhagic nephritis. Because of the persistent hematuria, a partial hysterectomy was performed.

The second patient, aged 38, had had three previous normal pregnancies. From the first month of her fourth pregnancy she began to pass blood in the urine, subsequently edema of the lower extremities developed. The urine contained red blood cells, leukocytes and casts. Cystoscopy revealed that the right ureteral orifice was edematous and that blood clots were being ejected from both ureters. The diagnosis was "primary nephrologic hematuria." Treatment consisted of rest in bed, diet, and the administration of calcium chloride. The urine continued to be tinged with blood, but the patient gave birth to a normal child, and both were in good condition at the time of discharge.

The third patient, aged 32, had had five previous pregnancies. From the second month of her sixth pregnancy the urine had been tinged with blood. Urinalysis in the third month revealed traces of albumin and some red blood cells. There were no urinary symptoms. The treatment consisted of injections of calcium chloride. The patient was discharged as cured nine days after treatment was begun.

In these three cases the author concluded that there could be no doubt that a previous nephritis had become acute again, owing to the state of pregnancy.

As I have previously stated, during the past four years I have seen 154 pregnant patients in urologic consultation, approximately 20 per cent of whom had, as a complication of their pregnancy, gross or microscopic blood in the urine. Hematuria, as considered in a review of the following cases, means that there was either gross blood in the urine or more microscopic blood than the occasional or few red blood cells found in the ureteral catheter specimen, such as might be expected as a result of trauma from the catheter.

Of the thirty patients studied, the average age was 27 years, the youngest being 16 years and the oldest 39. This was the first pregnancy for the one aged 16 years, with urinary tract complications at the fifth month of the pregnancy, and the third pregnancy for the one aged 39, with urinary tract complications at the sixth month of pregnancy. The greatest number of pregnancies had occurred in a woman, aged 25, this being her tenth pregnancy, with urinary tract complications during the second month of this pregnancy.

Of the thirty patients, this was the first pregnancy for sixteen, the second pregnancy for seven, the third pregnancy for four, the fifth pregnancy for one, the sixth pregnancy for one and the tenth pregnancy for one. Of the sixteen primiparas, the majority of the urinary tract complications developed between the sixth and the seventh month of pregnancy, however the average time of onset for the thirty patients was four and one-half months. In four of the thirty patients the urinary tract complications developed post partum, the onset being within forty-eight to seventy-two hours in three cases, and thirteen days in one.

Bladder symptoms, such as smarting and burning during urination and urgency, were present in all thirty cases. There were seventeen patients having definite

renal pain. Eight had bilateral pain. In six the pain was on the right side, in three on the left side. Renal pain was twice as frequent in the right renal area as in the left renal area, thus being significant of the preponderance of pyelitis of pregnancy occurring most frequently in the right renal pelvis.

The frequency of toxemia of pregnancy, as observed by the obstetrician, was not notable in this series of thirty cases, as only four showed evidence of renal insufficiency, and those only to a mild degree.

Gross hematuria was present in eighteen of the thirty patients, the remaining twelve had microscopic blood in the urine.

The origin of the hematuria in nine patients was from the urinary bladder, six had gross blood and three microscopic blood. From the right kidney the hematuria occurred in twelve cases and from the left kidney in eight cases.

Of the thirty patients, the charts show evidence of cultures of the bladder and the right and left kidney urine in only twenty-three, which is a deplorable record and one for which no excuse is offered. *B. coli* was the organism found in thirteen, *staphylococcus* in six, and mixed *staphylococcus* and *B. coli* in one. Three patients had normal cell counts and negative cultures of the urine. Two had an impacted calculus in the lower right ureter and one had gross blood from a megalo-ureter. In an attempt to evaluate the laboratory examinations in these twenty-three patients, the task is almost hopeless as, over a period of years, various technicians have been responsible. The greatest lesson to be learned is to have procedures of this kind so standardized from the technical point of view that irrespective of which technician does the work the reports will at least be uniform for study. Twenty of the twenty-three patients who had adequate urine studies showed the presence of a pyelitis. Very definite dilatation of the renal pelvis, to the extent that one would be justified in using the term hydronephrosis, occurred in ten patients. In two of these the dilatation was bilateral, and in two others a right pyonephrosis was found.

In ten of the thirty cases, roentgenograms were made in two postures, horizontal and vertical. Of these ten, five showed a right renal ptosis, one a left renal ptosis, and four a bilateral renal ptosis. Again these observations are not complete because of the absence of films made in the upright posture in all instances. In describing the existing conditions, I have used the term "megalo-ureter" for all dilatations from slight to dilatation the size of the small undistended intestine. Eleven cases of megalo-ureter were found to be present, the dilated ureters were bilateral in four, and there was dilatation of the right ureter in six, and dilatation of the left ureter in one. In two cases a calculus was found in the lower right ureter. Ureteritis was observed in two cases. In one the condition was bilateral, in the other it was confined to the right ureter.

In none of the cases was the urethra the site of the hemorrhage.

The complications and the end results in the thirty studied cases were as follows. One case, cholecystotomy and death. Autopsy in this instance revealed the cause of death to be acute fibrinous pericarditis. One case, intestinal obstruction and enterostomy followed by death, autopsy in this instance revealed a gangrenous peritonitis. One case, induced abortion in the third month. One case, therapeutic abortion followed by death from pulmonary embolus. Two cases ureterotomy followed by normal delivery.

SUMMARY

1 In a routine study of 154 urologic consultations because of urinary tract disturbance during pregnancy, hematuria occurred in thirty cases

2 Further study of these thirty patients revealed Cystitis in all cases

Pyelitis in twenty-two, of which twenty were bilateral and two were unilateral

Hydronephrosis in ten, two of which were bilateral and eight unilateral

Pyonephrosis of the right kidney in two cases

Ptois in nine cases, four being bilateral, four right and one left

Megalo-ureter in eleven cases, of which four were bilateral, six right and one left

Ureteral calculus of the right ureter in two cases

Ureteritis in two cases, one bilateral and one of the right ureter

3 Hematuria is a grave complication of pregnancy, and in all instances of hematuria occurring during pregnancy the very least the patient is entitled to is a thorough investigation by a competent urologist

ABSTRACT OF DISCUSSION

DR JOHN M BERGLAND, Baltimore At the Johns Hopkins Hospital, hematuria in pregnancy apparently occurs very rarely There have been only two cases in the last year in which there was macroscopic blood in the urine The patients had cystitis and not pyelitis Cystitis seemed to be the cause of the bleeding No specific treatment was necessary except that indicated for the bladder condition, and the patients recovered without further complication At several other hospitals in which I have access to the records, hematuria during pregnancy seems to be almost unheard of, and in my private practice I have noted it in only a few instances, and in those cases the symptoms cleared up without difficulty The presence of microscopic blood, of course, is often noted but in the great majority of cases this is a symptom of but little moment and is usually caused by some slight trauma, either by the presence of a stone in the ureter or by instrumentation for the treatment of pyelitis or cystitis As far as my experience is concerned, hematuria during pregnancy has no bearing on the toxemias found in that condition

DR JOSEPH B DELEE, Chicago I was called to do a cesarean section on a woman about 35 years of age whom I hadn't seen until that moment It was a clear case of placenta praevia The woman had gone through a normal pregnancy She wasn't in labor Everything was going along nicely when she suddenly began to bleed—a sudden painless, causeless uterine hemorrhage of the last trimester While I was getting ready for the operation, the nurse who was preparing the patient for the cesarean section reported that the blood was coming from both the vagina and the urethra So we washed out the vagina and got the clot out of it, and then we got pure blood by the catheter out of the bladder The cesarean section was postponed and the woman delivered herself the next day without any trouble Cystoscopic examination showed a little congestion of the trigonum

Fats Overheated in Cooking—All fats ordinarily used as food are almost completely digested and absorbed Large quantities of fat may cause digestive upsets by prolonging unduly the stay of food in the stomach, or, when cooked so as to form a coating over other foods, they may retard the action of the digestive enzymes Fats overheated in cooking may be directly irritating to the digestive tract These latter unfavorable effects, it should be pointed out, are not properly chargeable to fats themselves but rather to their wrong use in cookery—Sherman, H C. INTRASPINAL (SUBARACHNOID)
INJECTION OF ALCOHOL

FOR PAIN ASSOCIATED WITH MALIGNANT CONDITIONS
OF THE FEMALE GENITALIA

J P GREENHILL, M.D

AND

HERBERT E. SCHMITZ, M.D
CHICAGO

At least 75 per cent of all women who have carcinoma of the cervix die as the result of the condition Nearly all these women suffer severe pain during the latter part of the disease and in a large proportion of cases the pain is constantly present, both day and night, and is almost unbearable This is due to the fact that the sensory nerves become involved in the malignant growth There are at present three means of relieving this pain The first and the one almost exclusively used at present is the administration of derivatives of opium, chiefly morphine However, there are disadvantages to this form of therapy, particularly the necessity of giving constantly increasing doses as the patient's tolerance increases, the nausea and vomiting that some women experience, the idiosyncrasy of others, the excitement produced in some, and the expense for poor patients The second method of giving relief from pain is surgical and consists essentially of pelvic sympathectomy and chordotomy While the former operation is simple, it nevertheless necessitates an abdominal operation and it does not relieve all cases The latter operation is a serious one and requires the skill of a neurosurgeon The third means of relieving pain consists of blocking the nerves that conduct pain sensation This may be accomplished by a number of different solutions, but alcohol is the one most commonly used

The injection of alcohol into nerves for the relief of pain was advocated many years ago by Sicard,¹ but this procedure has not been employed for the relief of pelvic pain until recent years Reding¹ in 1925 suggested this form of injection for pain caused by inoperable carcinoma in the region innervated by the sacrococcygeal plexus Van Erps¹ in 1930 reported a series of sixteen cases of pelvic pain treated by the injection of alcohol into nerves and in the same year Condomin and Arnulf² reported five cases of pelvic cancer treated by such injections Reding, Van Erps and Condomin and Arnulf injected the alcohol directly into the nerve roots at the level of their exit from the spinal column In December 1930 Dogliotti³ recommended subarachnoid injection of alcohol for the relief of pain This suggestion was based on Lugaro's studies on the physiology of pain Among Lugaro's conclusions was a statement that, in order to relieve surgically pain due to neuralgia, it is not necessary to block or destroy all the involved sensory neurons It is essential only to produce a block or destruction of part of the fibers, the amount depending on the severity of the pain

Leriche and others deny the existence of peripheral fibers that convey pain sensations They maintain that the sensation of pain in the cerebral centers is due to

the transmission of sensory impulses by the nerves which convey general sensibility, particularly those which carry heat, cold and pressure sensation and to a lesser extent those of muscular and tactile sense. Ordinary stimulation of the heat, cold, pressure and other sensory fibers produces the sensation characteristic of each one but excessive stimulation of these fibers produces the sensation of pain. Hence it is Lugaro's contention that a simple reduction in the number of the peripheral sensory nerve fibers is sufficient to prevent the occurrence of a sensation of pain. With this theory Dogliotti agrees and on it he based his idea of decimating the peripheral nerve fibers in the posterior roots. He chose the subarachnoid space for this purpose because this region is the most central one for attacking the nerve roots. Injection in this region will prevent all painful peripheral stimuli from reaching the medullary centers, even if the stimuli act at the level of the spinal ganglions, the intervertebral foramina or the spinal roots.

Absolute alcohol was selected for injection by Dogliotti because the action of alcohol on nerve tissue has been known for a long time, it has no secondary toxic effects, it is easily and rapidly diffused, and it has a specific gravity much lower than that of the spinal fluid. As may be seen *in vitro*, absolute alcohol floats on top of liquor amni in a pure state for a few minutes.

Dogliotti treated forty-five patients by means of subarachnoid alcohol injections and he used between 0.2 and 0.6 cc for each injection. In some cases relief was immediately obtained whereas in others no effect was observed for from twenty to thirty days. About 10 per cent of his patients had to remain in bed for two or three days after the injection, and a large proportion suffered from headaches and backaches for a few days. Examination of the spinal fluid a few days after injection showed an increase in cerebrospinal pressure, a perfectly clear fluid and a slight increase in albumin and leukocytes in the sediment. After ten days, however, the cerebrospinal fluid was normal. Most of Dogliotti's patients had sciatic pains, but not one of them had carcinoma of the female genitalia. Yeomans⁴ reported the use of subarachnoid injections in cases of gastro-intestinal cancer. Saltzstein⁵ employed this procedure in eleven cases, eight of which were cases of

Fig 1—Attitude assumed by patient for subarachnoid injection to relieve pain on right side. The pillow elevates the lumbosacral region which is tilted forward and the dark line indicates the first lumbar interspace where the injection is to be made.

cervical carcinoma. These appear to be the first reported cases of cervical carcinoma so treated. There was only one failure among the eight cases. Saltzstein made his injections in the first and second lumbar inter-

spaces as did Yeomans. At about the same time Stern⁶ reported a series of fifty subarachnoid injections, of which twenty-six were for cancer in nineteen patients. Only five of these patients had carcinoma of the female genitalia and all were relieved by the alcohol injections. Stern obtained complete relief in 70 per cent of his cases, partial relief in 20 per cent and failures in 10 per cent. He observed better results when the injections were given in the upper lumbar interspaces and more

Fig 2—A cross section of spinal column when patient rests on her side but without ventral tilting. B the same cross section when the body is tilted ventrally. This position removes the anterior or motor roots from the field of the floating alcohol, which affects essentially the posterior or sensory roots and the dorsal root ganglions. (Slightly modified from Stern.)

satisfaction with absolute alcohol than with 95 per cent alcohol. Stern kept his patients on the side only ten minutes after the injections, whereas Saltzstein, Yeomans and Dogliotti kept their patients in this position for twenty minutes following the injection. To these thirteen cases of carcinoma of the female genitalia treated for pain by subarachnoid injection of alcohol we add twenty-five more.

TECHNIC OF INJECTION

Our technic for intraspinal (subarachnoid) injection is as follows. We prefer not to give any preliminary medication because we wish to observe the immediate effects of the injection. Most patients with advanced carcinoma of the cervix and other genital organs have much more pain on one side than on the other. The patient is placed on the side opposite to that on which most of the pain is present. A pillow or pad is placed under the pelvis and side to elevate the sacral and lumbar portions of the spine, the back is arched as much as possible, the body is turned somewhat ventrally and the head is lowered slightly (fig 1). By placing the patient in this attitude we raise the sacrolumbar region of the spine to the highest level and at the same time make the posterior or sensory nerve roots lie horizontally. The anterior or motor nerve roots come to lie in a plane that is usually out of reach of the alcohol (fig 2). Even if the motor nerves are not removed from the field of the alcohol they are not often affected because, as Sicard contended and Byrne⁷ confirmed, sensory nerves are more susceptible than motor fibers to the effects of alcohol.

Some one should hold the patient in the proper position. A weak solution of iodine or other antiseptic is applied over the lumbar and upper sacral regions.

Dogliotti recommended that the lumbar interspace chosen as the site of injection should depend on how high up the pain extended. In most of our early cases we selected the fourth lumbar interspace, and our results were highly satisfactory. We are now making our injections in the first lumbar interspace to relieve the pain that some women develop high up in the abdomen and back. An ordinary lumbar puncture needle with a stylet is used. The needle is injected into the desired interspace just as for an ordinary lumbar puncture, and we prefer not to use procaine in the skin before inserting the needle. After the needle is in the subarachnoid space, as evidenced by the flow of spinal fluid, 0.5 cc. of 95 per cent alcohol is injected into the cerebrospinal fluid. For this purpose it is best to use a tuberculin syringe so as to be sure that not more than 0.5 cc. is injected. Furthermore, the alcohol must be injected very slowly, drop by drop, about two minutes being taken for the injection of the 0.5 cc. This will avoid a mixture of the alcohol with the spinal fluid. The alcohol rises immediately to surround the posterior roots, because the specific gravity of alcohol is about 0.806 whereas that of the spinal fluid is 1.007 per cent. No attempt should be made to draw spinal fluid into the syringe to mix it with the alcohol, because this is exactly what is not wanted. After the injection is made the needle is withdrawn and the puncture hole covered with sterile gauze and adhesive plaster.

Before the injection is completed, the patient will complain that the upper leg feels numb or hot and that she cannot move the leg. The numbness is experienced almost as a routine after the injection but disappears spontaneously after a few hours or few days in most of the cases. In spite of what the patient says concerning her inability to move the leg, she can easily move it when requested to do so. At the same time that the patient informs us of the numbness she also often tells us either voluntarily or in answer to our query that her pain has disappeared. We have found that the longer the patient is permitted to lie on her side, the better are the results. Hence we now keep our patients on their side for two hours after the injection. Then we permit them to get up and walk around. Some find difficulty in getting up from a chair because their "leg is asleep." Sometimes the leg feels heavy and the patient experiences some trouble in walking up steps because the knee flexes readily. These sensations usually wear off in a few hours, although in some women they last a number of weeks. We have permitted all our patients who were ambulatory to go home within three hours after the injection and have observed no ill effects from this procedure.

If the patient has pain on both sides, an injection is made a week later with the patient lying on the opposite side. The same amount of alcohol is injected.

We have restricted subarachnoid injection of alcohol to patients with hopelessly advanced cancer. Until we know more about the effects of 95 per cent alcohol on the spinal cord we shall not extend the use of this procedure to other cases, except perhaps for unusual circumstances.

ANALYSIS OF RESULTS

We have performed twenty-seven subarachnoid alcohol injections in twenty-five women. Two women had two injections on opposite sides.

Our patients ranged between the ages of 31 and 58, and the carcinomas were of the cervix in twenty-two, of the clitoris in one, of the vulva in one and of the ovary in one.

At the time of the injection, the patients had the following complications: "frozen pelvis," twelve, invasion of inguinal glands, three, and one instance each of rectovaginal fistula, vesicovaginal and rectovaginal fistula, invasion of the bladder, invasion of the bladder and rectum, invasion of the labia, and radiation bladder ulcer.

The locations of the pain for which the injections were made were as follows: on one side of the pelvis and down the posterior thigh, six, in the sacro-iliac joint and down the thigh and leg, five, in the lower part of the back and down the leg, three, on both sides of the pelvis and down the legs, three, in the hip and leg, two, and on one side of the pelvis, in one thigh and leg, in the vagina, labium and lower spine, in the vagina and thigh, in the bladder and in the rectum, one case each.

For twenty-one injections we used 0.5 cc. of 95 per cent alcohol, for four injections we used 0.75 cc. and for two we employed 1 cc. We kept the patients on their side for twenty minutes in five instances, for one hour in twenty cases, and for two hours twice. We made most of the injections in the fourth lumbar interspace but are now making all of them in the first interspace.

Our results show that twenty women were completely relieved of their pain, three were partially relieved, and in two cases the injections failed. One of the failures was subsequently overcome by repeating the injection in a higher lumbar interspace. The other failure occurred in a woman who had previously had a pelvic sympathectomy which relieved her for six weeks. Then the pains returned. She was given 1 cc. of alcohol first on the left side and two days later on the right side but she obtained no relief. Atrophy and anesthesia of the left leg developed. This condition was most likely due to the large amount of alcohol injected and perhaps also to the short interval between the two injections. This case was one of our very early ones and was the only case in which we used such a large amount of alcohol and repeated the injection within such a short time. Autopsy on this patient revealed the cause of failure. The patient had bilateral pyonephrosis, which could not have been relieved by the alcohol injections made in the fourth lumbar interspace. Had we made the injection in the first interspace, the patient might have been relieved of her pain.

Thus far, of the twenty-four patients who have been relieved of their suffering, two have been free from pain for six months, one for five months, one for four and a half months, three for four months, two for two months, four for six weeks, four for four weeks, four for three weeks, and three for two weeks.

The complications that followed the alcohol injections were numbness of the leg for three days, six, numbness of the leg for more than three days, six, and in one case each, urinary retention for two days (had bladder invasion of carcinoma), urinary incontinence the first night, pollakiuria, "leg cold at night," paralysis of the leg for one and one-half hours, anesthesia and atrophy of the leg, and diarrhea for twenty-one days.

CONCLUSIONS

Our experience with twenty-seven subarachnoid injections of alcohol in twenty-five women with advanced carcinoma of the genitalia leads us to recommend this procedure in all women who suffer from excruciating and persistent pain that is associated with

genital carcinoma This injection is simple to carry out, it entails very few risks, and it has brought relief to twenty-four out of our twenty-five patients Because it is simpler than any operative procedure and because the results are so satisfactory, we are now using it in preference to pelvic sympathectomy, which we advocated two years ago for the same purpose We shall resort to sympathectomy in the cases in which alcohol injections fail Until we know more about the late effects of 95 per cent alcohol on the spinal cord itself, it is best to restrict subarachnoid injections to patients in whom the malignant condition is far advanced

CONGENITAL SYPHILIS

THE RESULTS OF TREATMENT IN CHILDREN

FRANK R SMITH Jr., M.D.
BALTIMORE

All the case records of patients with congenital syphilis seen in the Harriet Lane Dispensary of the Johns Hopkins Hospital from its opening in 1914 until June 1934 have been studied, with special emphasis on the end results of treatment There were 991 patients in all, of whom 621 had early congenital syphilis and 370 the late form An arbitrary dividing line of two years of age is made between the early and late groups In the study of the therapeutic results, no patient was included unless he had been followed for at least two years Many had been under treatment and observation for as long as fifteen years Babies remain under the care of the obstetric service until they are 2 weeks old, and all patients in the Harriet Lane Dispensary on reaching the age of 15 years are transferred with their records to the adult clinic regardless of the length of observation Thus in this series neither the babies dying in the obstetric wards nor those suffering relapses after puberty are included, so that in this respect the data are not complete and therefore not entirely representative for congenital syphilis as it actually occurs in the community

Of the 991 patients there were approximately 70 per cent Negroes and 30 per cent white There were slightly more females than males The mean age of admission for babies with early congenital syphilis was 3.3 months and for the late group 7.9 years

EFFECT OF ANTEPARTUM TREATMENT

The effect of antepartum maternal treatment on the incidence and severity of lesions in the syphilitic children was made the subject of particular study No treated mothers who bore congenitally syphilitic children had had over fifteen injections of arsphenamine during the pregnancy The more treatment given the mother, the less was the incidence of lesions in the child The percentage incidence was 80 for the children of untreated mothers as compared with 64 for those of mothers who had received some, though inadequate, antepartum treatment Likewise no relapse occurred in any of those children whose mothers had been given antepartum treatment, and only 4.7 per cent

(about one fifth of that of the group as a whole) remained Wassermann fast at the end of the observation period

During the last decade, when more attention has been paid to the routine treatment of mothers during their pregnancy and more reliance has had to be placed on serologic reactions and x-ray studies of the bones for early diagnosis in the child, there has been a noticeable decrease of children with florid lesions of congenital syphilis The two decades covered by this paper show the contrast of the two periods The first, from 1914 to 1924, was the one in which few mothers received any and most children received wholly inadequate treatment and most of the children showed lesions, in the second, from 1924 to 1934, the treatment given both mother and children was more thorough and the number of patients with syphilitic lesions was less

METHOD OF TREATMENT

The treatment scheme for both early and late congenital syphilis has varied greatly in the past two decades with the introduction of newer drugs of both the arsphenamine and heavy metal groups, and with changing ideas about rest periods That in use since 1928 has been the continuous method, with courses of an arsphenamine alternating with courses of a bismuth compound, each calculated for age and weight With small babies and those children with poor veins, the arsphenamine chosen is sulpharsphenamine, with the older children neoarsphenamine, and silver arsphenamine in special cases The bismuth preparation is the salicylate, 10 per cent suspension in oil, given intragluteally, and has all but entirely replaced the mercury preparations formerly used Only rarely is the old inunction prescribed Even in small premature infants a bismuth compound is employed Malaria, tryparsamide and potassium iodide have been used for special indications Up to this time acetarsone has not been tried Each course of treatment consists of six or eight injections, there are no planned rest periods, and treatment is continued for a minimum of a year or for at least fifty injections (twenty-five of each drug) Whether treatment is carried further depends on the presence of active lesions and on the Wassermann response In Wassermann-fast patients, probation is not allowed until the spinal fluid is found to be normal, and in such cases treatment is continued for an arbitrary minimum of two years (100 injections) The justification for the prolongation of treatment in Wassermann-fast patients lies in the fact that relapse or progression is four times as common in such individuals with early congenital syphilis as in those in whom Wassermann reversal is secured by treatment The limitation of from one to two years of treatment does not apply to those children who show persistent active lesions, especially interstitial keratitis and involvement of the central nervous system

With deliberate intent to avoid the word "cure," the term "ultimate clinical outcome satisfactory" has been used By this term is meant that the patient at the end of the observation period is for all practical purposes well, free from symptoms, and may lead a normal life Irremediable stigmas, such as old inactive corneal scarring, healed perforation of the nasal septum or even a positive blood reaction may persist, but all these signs are asymptomatic and in no way affect his activities

In tabulating the amounts of treatment received by each patient the terms "inadequate," "moderate" and

Read before the Section on Dermatology and Syphilology at the Eighty-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., June 13, 1935

From the Departments of Pediatrics and Medicine of the Johns Hopkins University School of Medicine and the Harriet Lane Home and the Syphilis Division of the Medical Clinic of the Johns Hopkins Hospital

"adequate" have been used, representing less than thirty, from thirty to fifty and over fifty injections respectively. It is felt that this procedure gives a better measure for comparison than if the total amounts of drugs given were used, since the doses vary more in children than in adults, in whom the amounts are more or less standard. "Relapse," in this paper, means that a fresh active lesion appeared after treatment had been started in a patient in whom all previous symptoms had disappeared and any previous one healed. "Progression" signifies that the lesion present continued and became worse during treatment and the observation period. This actually refers exclusively to central nervous system involvement, because it was found that all the other syphilitic lesions responded with more or less readiness to treatment.

DEATHS

There were 169 deaths (27 per cent) among the 621 patients admitted with early congenital syphilis. Syphilis could be considered the direct cause of death in sixty, or 35.5 per cent. More than 90 per cent of these were in children less than 6 months of age. The number of deaths truly attributable to syphilis was found to decline rapidly with age and with the amount of treatment given. Only one child with early congenital syphilis followed for more than two years died primarily of this disease, and all but fourteen of the total 169 deaths were of children under 2 years of age. A number of patients arrived at the clinic in an almost moribund condition, so that effective treatment could not be administered. If the baby had received even one course of treatment, typical lesions of syphilis were not found at necropsy. Only 5.5 per cent of those who died had received more than six injections.

There were twenty-three deaths in the group with late congenital syphilis. Of these, eleven were attributable to syphilis, all of the central nervous system. Only three had had adequate treatment.

It may be said then that congenital syphilis, excepting when the central nervous system is involved, is rarely if ever the cause of death in a child that has had more than four courses of treatment, and that in young babies death usually occurs because of other complicating illnesses that do not allow the antisymphilitic remedies to have an opportunity to arrest the infection. Death from congenital syphilis per se is very rare in any patient born of a mother who has had even one course of antepartum treatment.

SEROLOGIC REACTIONS ON ADMISSION

The blood Wassermann reaction was positive on admission in all but five of the patients. In these, other signs of the disease and facts of the family history were sufficient to make the diagnosis of congenital syphilis unmistakable.

The spinal fluid has not been examined in a routine way in every patient. It was examined in sixty-one instances in the early group and in seventy-one in the late group at the time of admission. It was found to be positive in twenty-one of the former (33 per cent) and thirty-six (50 per cent) of the latter. The total gives an incidence of central nervous system syphilis of approximately 10 per cent of the total number of cases. The existence of a positive fluid in small babies is not as significant for the development of subsequent nervous system disease as when found in children over 2 years of age. Only one of the babies with early congenital syphilis still had a positive fluid when

reexaminations were made at some time during the observation period, and two that originally were negative had become positive.

Of the sixty-one babies of the early group whose fluids were examined, twenty-two died before they were 2 years old. Of these the number with positive fluids was slightly greater than of those whose fluids were negative. In the late group, six of the seventy-one with abnormal fluids died of dementia paralytica before they had been followed for a year. None of those in this group with originally negative fluids developed positive fluids at a later examination.

At some time during the observation period, though not at the time of admission, twenty-five additional patients with early and fifty-four with late congenital syphilis were examined by lumbar puncture. This was done either for signs suggesting central nervous system involvement, because of Wassermann fastness, or as a part of a diagnostic work-up. None of those in whom the Wassermann reaction was the only indication of syphilis showed any alteration of the spinal fluid. Fifteen of the seventy-nine patients had clinical signs that were interpreted as meaning neurosyphilis. In only four of these fifteen patients was the spinal fluid found to be positive for syphilis. These four patients were diagnosed as having tabes or juvenile dementia paralytica and the other eleven were classified as having late congenital syphilis with mental deficiency. The term neurosyphilis has been used strictly to include only those patients who at one time or another had positive serologic evidence in addition to positive clinical signs. There were four instances of patients having a positive spinal fluid without clinical evidence of central nervous system involvement.

RESULTS OF TREATMENT

The results of treatment will be considered in several ways: the effect on the disappearance of lesions and on the incidence of relapse and progression, the ultimate clinical outcome, and the effect on the Wassermann response.

In congenital syphilis there are three age periods when lesions are most prevalent: (1) from 1 to 6 months, (2) from 6 to 8 years, and (3) at puberty. In the first period the lesions are equivalent to those of early acquired syphilis, i.e., chiefly ectodermal, mucocutaneous and osseous, all of which heal rapidly under not more than two courses of treatment. In the second period occur chiefly osteitis and periostitis, especially of the tibia and nasal septum, interstitial keratitis and in a few instances central nervous system involvement. In the third are common interstitial keratitis, eighth nerve deafness and neurosyphilis. Periostitis responds well to treatment, if of the nasal septum, the active process is arrested though the perforation may remain. Nerve deafness was not encountered in this group of young patients, all of whom had had treatment before puberty. Interstitial keratitis more often than not was very resistant to treatment and required from twelve to fifty injections for its relief. Neurosyphilis alone failed to give a satisfactory clinical response in 90 per cent of the patients, even after a complete serologic reversal.

The incidence of relapse in the group with early congenital syphilis was 9.4 per cent, or twenty-six of 279 patients. As far as can be determined with the means available, the incidence of relapse was less as the

amount of treatment was increased. Several patients who had had irregular, though in the sum total adequate, treatments (more than fifty injections) did return with a relapse after a lapse of several years. The relapses were scattered in type but were most frequently interstitial keratitis.

The incidence of relapse in the late group was higher, 13.2 per cent, or thirty-two of 242 patients. The ultimate clinical outcome was in general more satisfactory as more treatment was given. Of thirty-two patients who relapsed during the earlier part of treatment, fourteen obtained a completely satisfactory clinical outcome after treatment had been continued.

In the early group, no patient with adequate treatment had a relapse when the serologic reactions were negative. Of the late group seven, or 22 per cent, did have a relapse or progression, two of these developing interstitial keratitis and five progression of central nervous system involvement. It thus seems that it is safe to place on indefinite probation any patient whose treatment was started before the age of 2 years and was adequate, who has no active lesion, and whose blood Wassermann and spinal fluid reactions are negative.

The question of the Wassermann response resolves itself into an analysis of Wassermann fastness. This phenomenon varies with the age at the start of treatment. Serologic reversal was obtained in 77 per cent of the patients whose treatment was started under the age of 6 months and decreased steadily with increasing age to only 16 per cent when the start of treatment was delayed until from 11 to 15 years. It was determined also that the percentage of Wassermann-fast patients varied with the total amount of treatment received during the first year of treatment rather than on the aggregate received during the whole observation period.

OBSERVATIONS

1 Early congenital syphilis is "curable." The start of treatment at an early age is an important factor, as is the amount of treatment given in the first year. It is safe to say that a baby whose treatment is started under 6 months of age has an 84 per cent chance of serologic as well as clinical "cure," if fifty injections of drug are given before the age of 2 years.

2 The incidence of relapse increases with the age at which the treatment is started and decreases with the amount of treatment.

3 Syphilis per se, except when the nervous system is involved, is rarely a cause of death in children over 6 months of age or in infants younger than 6 months who have had more than one course of treatment.

4 All clinical manifestations of congenital syphilis respond to antisyphilitic treatment except neurosyphilis, in which progression may occur in spite of it and even after the serologic reactions are negative.

1014 St. Paul Street.

ABSTRACT OF DISCUSSION

DR. E. J. TROW, Toronto. Antepartum care is of prime importance in the prevention of congenital syphilis. In centers where antepartum clinics are established one sees extraordinarily good results, and the lowered incidence of congenital syphilis as noted in children's hospitals is proof of this. Once a child is infected every effort must be put forth in arriving at an early diagnosis and immediately administering treatment. Only when treatment is not given until a considerable length of time has elapsed are serious degenerative changes found. Dr. Smith's results correspond almost exactly with the results obtained at the Hospital for Sick Children in Toronto. The

only suggestion I can make is that acetarsone or some such remedy be given by mouth to the premature infants who are not able to stand the more concentrated arsenicals. This saves time and allows the infant to gain sufficient strength before arsenical injections are administered. In Toronto great satisfaction is felt because of the marked decrease in congenital syphilis noted in the wards. In fact the Wassermann test is no longer made as a routine procedure except for older and chronically ill children, as it is seldom that this procedure elicits more information than does the clinical evidence except in older children. Along with the decreased incidence of congenital syphilis in the Hospital for Sick Children there has been a marked decrease in syphilis among adults in the Toronto General Hospital. From a percentage of 12 of admissions to the wards of patients with syphilis in 1913 to that of 17 per cent in 1934 is an excellent demonstration of the value of the clinics where treatments are given.

DR. ADOLPH ROSTENBERG, New York. I should like to refer to an instance in which syphilis affected members of three generations. An American woman, about 35 years of age, had two children and was pregnant when at antepartum examination it was found that she showed a positive Wassermann reaction. The new-born infant was examined and also showed a four plus Wassermann reaction. In this woman's 6 year old son paraplegia developed when he was 2 years old and he was treated at one of the leading orthopedic hospitals, but a Wassermann test had not been made. The 4 year old son was apparently healthy. When it was found that the mother was syphilitic, the two older children were examined and they both showed a four plus reaction. The mother did not know very much about her father, but she brought her mother, aged about 56, to the clinic. She was found to have active syphilitic lesions and a four plus Wassermann reaction. I went into the history of the daughter and felt convinced that she had inherited syphilis from her mother and that she had not acquired it. The daughter's husband was examined repeatedly. Three Wassermann tests were negative, and he had no syphilitic stigmas. What should be the treatment of the children in the third generation? All had a four plus Wassermann reaction. The oldest boy has stigmas but the others do not. I am giving them all antisyphilitic treatment. Has Dr. Smith seen cases of syphilis in a third generation and should the treatment be similar to that given in the ordinary congenital cases?

DR. FRANK R. SMITH, JR., Baltimore. I think that the few patients with syphilis of the third generation should be treated as are the congenital syphilitic children. The problem is how much treatment should be given the child with latent syphilis, that is, the child who presents the positive Wassermann reaction and nothing else. I feel that a treatment of at least 100 injections will prevent the development of interstitial keratitis, syphilis of the central nervous system and deafness due to involvement of the auditory nerve. Certainly two years' treatment is warranted in order to prevent the development of some of the serious irremediable stigmas. Acetarsone has not been tried at the clinic, as it has not been felt that the social service department is sufficiently well organized to make absolutely certain that the doses are given. As with the mercury injections, one is never sure that the amount prescribed has been used. It is hoped that acetarsone can be tried in the next year or two when it can be assured that each dose will be administered. To me the study of congenital syphilis has been an excellent hobby. The running of a clinic should be the job of a full-time physician who plans to remain at the clinic. The disease is becoming less interesting academically because fewer lesions have been seen in the last decade than before and one had had to depend more on roentgenograms and serologic reactions for diagnosis. I do believe that congenital syphilis is comparable, with minor variations as to types of lesions, with acquired syphilis and that the same problems that prevail in latent and asymptomatic neurosyphilis in the acquired form carry over also to congenital syphilis. It is useless to treat the patient with late congenital syphilis with an occasional dose of antisyphilitic medication, either give thorough, adequate treatment or none at all.

TREATMENT OF INTRACTABLE NASAL
HEMORRHAGE BY INJECTIONS OF
MOCCASIN SNAKE VENOM

SIMON DACK, MD

Research Assistant in the Cardiovascular Laboratory of the
Mount Sinai Hospital
NEW YORK

The use of moccasin venom for the treatment of bleeding was introduced by Peck in 1931. The rationale of this form of treatment was based on the observations of Peck and Sobotka¹ in 1931 that animals could be made resistant to the experimental purpura known as the Schwartzman phenomenon by previous injections of moccasin venom. Since Peck could not demonstrate any circulating antibodies in the blood serum that would explain this antihemorrhagic effect, and since large doses of antivenin did not influence the course of the Schwartzman phenomenon, he deduced that the antihemorrhagic effect was probably produced through a direct action on the vessel walls.

In studying the factor or factors in moccasin and other snake venoms that were responsible for the resistant state in rabbits as far as the Schwartzman phenomenon was concerned, Peck² observed that the antihemorrhagic factor was entirely independent of the neurotoxins and hemorrhagins in the venoms. Even individual moccasin snakes varied in the content of this antihemorrhagic factor. Furthermore, he seems to have shown in his experimental animals that the antihemorrhagic effect was not due to a foreign protein effect in the broad sense of the term, since the addition of antivenin or even normal horse serum neutralized the antihemorrhagic factors in the venom.³

In 1932 Peck⁴ reported the results of his treatment of hemorrhagic diseases with moccasin snake venom (*Ancistrodon piscivorus*). His clinical results seem to substantiate the premise that the moccasin venom exerted its therapeutic effect through an action on the blood vessel walls. In these cases there was cessation of hemorrhage, although the platelet count did not rise and the clotting factors of the blood were not appreciably influenced. Since this favorable report, Peck has extended the use of snake venom therapy to many hemorrhagic conditions, including functional uterine bleeding,⁵ the Henoch-Schönlein syndrome, epistaxis, thrombocytopenic purpura, and other cases of blood dyscrasia in which hemorrhage is a leading symptom.⁶

The method of treatment as described by Peck consists of subcutaneous injections of moccasin snake venom (*Ancistrodon piscivorus*) in 1:3,000 dilution (The venom may now be obtained from the Lederle Laboratories, New York). The initial dose for adults is 0.3 cc, which is rapidly increased to 1 cc, given twice weekly. The injections are continued for at least three months, and with the appearance of a ther-

apeutic effect the interval between injections is gradually increased to from two to four weeks. In about 50 per cent of cases a local sensitivity to the proteins in the snake venom appears after the fourth or fifth injection, manifested by local edema, discoloration and itching. Peck⁷ has devised an effective method of desensitization, which consists in reducing the dose to 0.4 cc of 1:10,000, 0.1 cc of 1:6,000, 0.4 cc of 1:6,000, 0.1 cc of 1:3,000, and finally 0.4 cc of 1:3,000 dilution. This method has succeeded in abolishing the local reaction in nearly all the cases in which sensitivity developed.

I have recently had the opportunity of observing the effects of snake venom injections in two cases of nasal bleeding. The two patients (one of whom is myself) were members of the intern staff of the Mount Sinai Hospital, New York, at the time Dr. Peck introduced this new form of therapy. Both cases will be described in some detail, because this is the first report of the successful use of snake venom in intractable nasal hemorrhage. Furthermore, the two patients were physicians who were able to follow their own clinical course more accurately than the ordinary layman can. In both instances the therapy was under the direct supervision of Dr. Peck.

REPORT OF CASES

CASE 1—The author, aged 27, has had frequent epistaxis since childhood. There is no familial history of bleeding. Until the age of 20 the nasal hemorrhages occurred either spontaneously, during an infection of the upper respiratory tract or after slight trauma, most often from the right nostril and occasionally from the left. During the five years prior to snake venom therapy, there was (almost daily) spontaneous nasal bleeding which was often very profuse.

Examination of the nose in 1929 revealed a septal deviation to the right, an atrophic rhinitis and a small ulceration on the right side of the septum, which was seen to be the site of the bleeding. The ulceration of the mucous membrane was considered the result of local irritation and pressure secondary to the deviation of the septum. Local treatment of the ulcerated area at this time with epinephrine ointment and other astringents was effective only for a few weeks. An attempt was then made to cauterize the bleeding area with trichloroacetic acid, but this therapy was also unsuccessful and the nasal bleeding recurred with increasing frequency and severity.

Reexamination of the nose in 1932, by Dr. Rudolf Kramer, showed the same condition previously noted. A study of the blood at this time revealed that the hemoglobin, red and white cells, platelets, bleeding and clotting times were normal. Cauterization of the bleeding area on the septum with a caustic was attempted several times in November 1932 but again was ineffective. An intranasal operation (submucous resection) was then advised as the only means of controlling the intractable hemorrhage.

Injections of snake venom were instituted in January 1933 by Dr. Peck. The initial dose was 0.3 cc of 1:3,000 dilution, given subcutaneously into the arm. The dosage was rapidly increased to a maximum of 1 cc injected twice weekly, a different site being used at each injection. After the fifth injection local sensitivity to the venom developed, manifested by redness and edema at the site of injection. Desensitization was rapidly carried out by a modification of the routine method described by Peck.⁸ The dosage was reduced to 0.05 cc of 1:3,000 and at each subsequent injection was doubled, until the original dose of 1 cc. was again reached. Desensitization by this method was achieved in about five injections. The therapy was continued for five months. During the first two months, 1 cc was given twice weekly. During the third month only one injection was given weekly, and during the last two months the interval between injections was increased to two weeks. The last injection was given on May 31, 1933.

7 Peck, S. M. Sensitization and Desensitization in Man with Snake Venom. *Arch. Dermat. & Syph.* 27: 312 (Feb.) 1933.

It required about three weeks of treatment before any definite diminution in bleeding was noted. Then on January 30 the bleeding suddenly ceased for ten days. This was the first time in five years that such a long free interval had occurred. The bleeding subsequently recurred about once in from three to seven days but was comparatively slight. From March to July 1933 a nasal hemorrhage occurred only once every two to three weeks. From July 1933 to the present time (December 1934), a period of eighteen months during which snake venom injections have been entirely discontinued, there has been only an occasional nasal hemorrhage, which occurred usually during an infection of the upper respiratory tract and which ceased readily within a few minutes.

It is interesting to note that a nasal examination in July 1933 (six months after the institution of snake venom therapy) revealed no essential change in the local condition, despite the complete cessation of bleeding. However, in a more recent examination (December 1934) the ulcerated bleeding area on the nasal septum was seen to be entirely healed.

CASE 2—H J, a physician, aged 27, had frequent nosebleeds since the age of 5. During boyhood the bleeding occurred irregularly, the intervals between attacks varying from several weeks to several months. The attacks usually lasted for several hours. After the age of 20 the hemorrhages became more frequent and more severe and were difficult to control. The periods of bleeding now lasted from several hours to several days. The bleeding occurred with equal frequency from the right and left nostrils. There was no familial tendency to bleeding.

The general physical examination in this case was negative at all times. Examination of the nose at the age of 14 revealed numerous small ulcerations of the mucosa on both sides. These areas were seen to be the source of the bleeding. Reexamination of the nose in 1932 revealed a similar condition. The ulcerated areas were considered by the rhinologist to be too numerous to cauterize.

In January 1933, after a free interval of several months, the epistaxis recurred with increased severity. The bleeding was quite profuse and difficult to control with pressure or local applications. Since no other conservative therapy was available, it was decided to study the effect of moccasin venom injections in this case. This therapy was instituted two weeks after the onset of the daily hemorrhages. The patient received a total of four injections of moccasin venom subcutaneously at weekly intervals. The initial dose was 0.5 cc. of 1:3,000 dilution and this was increased to 1 cc. in subsequent injections. The nasal bleeding ceased spontaneously after the first injection. After the fourth injection a local sensitivity developed at the site of injection manifested by moderate itching and edema. As the nasal bleeding had already ceased entirely four weeks prior to this, the patient received no further injections. Despite the early discontinuation of the injections he remained free from all bleeding for a period of eight months. During the past twelve months he has had only three attacks of bleeding which were very slight and ceased within a few minutes.

COMMENT

The two cases reported are of special interest because the patients were physicians who were able to follow their clinical course closely and to evaluate critically results of the therapy. In both cases the injections of snake venom were instituted after other conservative measures had failed. In case 1 a submucous resection was advised as the only effective means for controlling the nasal bleeding, as the presence of the bleeding area in the mucous membrane was considered secondary to the deviation of the nasal septum. In case 2 the sites of bleeding in the mucosa were so small and so numerous that surgical intervention was contraindicated.

There was a marked beneficial effect in both cases following the injections of snake venom. A definite therapeutic effect became manifest in case 1 in three weeks. Thereafter the nasal bleeding rapidly diminished in frequency and severity over a period of three months and then ceased almost entirely. The anti-

hemorrhagic effect of the snake venom has persisted for a period of two years. In case 2 there was almost an immediate cessation of bleeding following the first injection. Despite the discontinuation of therapy following the fourth injection, the antihemorrhagic effect of the venom lasted for eight months. The few slight recurrences may have been due to the wearing off of this effect because of too few injections. Should the hemorrhages continue to recur, a second course of injections will be instituted.

SUMMARY

In two cases of epistaxis of many years' duration occurring in two physicians, in which other conservative measures were ineffective, injections of moccasin snake venom (*Ancistrodon piscivorus*) seem to have been effective in controlling the bleeding. In both cases there has been almost a complete cessation of bleeding during a period of eighteen months, although injections have been discontinued.

SEX DETERMINATION, SEX DIFFERENTIATION AND INTERSEXUALITY

WITH REPORT OF UNUSUAL CASE

EMIL NOVAK, M.D.

BALTIMORE

There is no more interesting biologic or clinical problem than that of intersexuality. What, as a matter of fact, does one mean by sex? Biologists answer that there is no such biologic entity and that the concept of sex is confused with that of the sexes. The latter term, again, merely indicates our concept of what constitutes maleness on the one hand and femaleness on the other, and opinions are quite apt to vary on this point. To begin with the absurd, a visitor to earth from some sexless planet might soon deduce that the males of our population are those wearing trousers and the females those wearing skirts. The trousered Marlene Dietrich on the one hand and the kilted Scotch Highlander on the other would later convince him of the fallacy of such a generalization.

Such sex attributes as hair distribution, character of voice and body contour are certainly unreliable criteria, for many females of the "virago" type exhibit extensive hairy overgrowth, possess deep voices and show the large frame, flat breasts and angular body contour commonly associated with the male. Conversely, one sees the effeminate "pansy" type of man, with little or no beard, a rounded figure, large fat breasts, and a soft, high-pitched voice. In short, there are few 100 per centers among human beings from this standpoint, there being a bit of the feminine in all men and a corresponding tinge of the masculine in all women.

The external genitalia are not safe criteria in the distinction between the sexes, for typically female external organs have been found in individuals in whom the gonads, and perhaps the only gonads, were testes. Furthermore, in some intersexual conditions it is difficult to determine whether the external genitalia are primarily of male or of female type.

Even the character of the gonads, on which the decision of actual sex has been commonly based in doubtful cases, is an incorrect criterion, as the biologic

From the Gynecological Department, Johns Hopkins Medical School. Read before the Section on Pathology and Physiology at the Eighty Sixth Annual Session of the American Medical Association, Atlantic City, N. J., June 14, 1935.

studies of recent years have shown. It is really this consideration, more than any other, that has served as the incentive for the writing of this paper. The usual classification of hermaphrodites and pseudohermaphrodites, that originally suggested by Klebs, is based on the concept of gonadal characters, and, if recent studies of sex determination and sex differentiation are to be accepted, this classification is incorrect and should be abandoned.

It is my purpose in this paper to review, at least sketchily, some of the newer biologic points of view concerning the general question of sex, more particularly as they bear on clinical problems in the same field. Biologic knowledge in this field is still lamentably incomplete, and the study of this question involves methods of approach which those of us who are primarily clinicians do not find it easy to grasp. And yet certain general truths seem to be crystallizing out fairly sharply, and familiarity with these should be of great practical interest and value to the clinician.

Before discussing the factors concerned in sex determination and sex differentiation, I will report briefly an unusual case, because, aside from its rarity, it illustrates the mingling of anatomic, physiologic and psychic attributes so characteristic of intersexuality. It will thus constitute a good starting point for the discussion.

REPORT OF CASE

History—A college student, aged 19, had been looked on in early life as a fairly normal girl. The family history is not significant, and she has two normally developed brothers. Aside from an attack of bronchopneumonia at the age of 2 years and a hernioplasty at the age of 8, she had enjoyed good health. The surgeon who performed the hernioplasty is quite sure that nothing else was done at this time and that no gonadal tissue was removed. The first suspicion of abnormality arose when she failed to menstruate at the usual age, and with each succeeding year she had become more imbued with the idea that she was in some way different from other girls, especially as other heterosexual body attributes made themselves evident. As a child, however, she had played with dolls, and her playmates had been girls. As she developed, all her instincts had been typically feminine. She had well marked libido toward males and had frequently noted turgidity of the clitoris. She had a strongly developed maternal instinct, her mother remarking that the patient had often expressed a longing for the time when she might have a home and children of her own. She had never menstruated. Her mother consulted Dr. Raymond O. Hitchcock of Alfred, N. Y., to whom I am indebted for the opportunity of studying and treating this patient.

Examination—The patient (fig 1) is 6 feet 1 inch (185.5 cm) in height and weighs 147 pounds (66.7 Kg). The body contour is rather angular, the shoulders are rather broad, and the muscles are well developed. There is a moderately heavy growth of hair on the upper lip, the upper part of the abdomen and the extremities, with a masculine type of crines. The breasts are flat and undeveloped. Mentally the patient is quite alert and highly intelligent. The voice is of a deep baritone masculine pitch. The external pelvic measurements are as follows: interspinous 25.5 cm, intercrural 29.5 cm, intertrochanteric 32.5 cm, external conjugate 18.0 cm, and bi-ischial 4.5 cm.

On examination of the external genitalia, the most striking feature was the marked hypertrophy of the clitoris, which measured 6.5 cm in length (fig 2). The glans was large and broad, measuring nearly 2 cm in diameter, and was almost entirely concealed beneath a well developed prepuce. It was obviously not a hypospadiac penis, for the normal looking meatus was situated more than 1 inch posterior to it. The labia majora and minora were both well developed and the former were covered with a heavy growth of hair, which extended outward to the perineum and buttocks. No gonads were palpable in the labia or inguinal canals. There was a very small

vaginal orifice protected by an intact annular hymen. An instrument introduced into the orifice passed in for a distance of 3.5 cm, the vagina ending blindly at this point.

Rectal examination showed an apparently complete absence of the uterus, although two oval bodies, evidently the gonads, could be palpated at the usual site of the ovaries. Roentgen studies of the pituitary were negative, the sella turcica being slightly smaller than normal. Similar studies of the adrenal were likewise negative. The Aschheim-Zondek test was negative, but qualitative study of the urine showed the presence of estrogenic substance. An exploratory laparotomy was considered advisable, to determine the nature of the gonads and the presence or absence of other abnormalities.

Operation—A medium suprapubic incision revealed an unusual picture in the pelvis (fig 3). There was a complete absence of the uterus and tubes. The bladder occupied its usual location anteriorly. Behind it there was a rather sharp ridge of peritoneum (plica vesicalis) stretching from one wall of the pelvis to the other. It was made up only of a double thickness of peritoneum, with nothing in its folds to suggest muellerian structures. Laterally this ridge merged into a somewhat triangular broad ligament-like structure with its base toward the pelvic wall. From its narrow median border there hung on each side a gonad which grossly suggested testis rather than ovary, measuring 3 by 2 by 2 cm. The surface of each gonad was white and perfectly smooth. Curled over each gonad was a structure that grossly suggested an epididymis (fig 4).

There was no sign of uterus, tubes or upper vagina. A careful search for possible other gonads or other abnormalities was made in the pelvis, broad ligaments, inguinal regions, retroperitoneally and along the ovarian vessels, but none were found. The adrenal glands were palpated, with no evidence of enlargement or neoplasm. There was, however, an incomplete descent and rotation of the cecum which, with the appendix, was found in the right upper quadrant.

A small wedge of each gonad was excised for frozen sections. When the gland was cut into, a rather dense albuginea-like capsule was encountered, and beneath this the tissue was found to be rather pulpy, not in any way suggesting the consistency of ovary (fig 5). It was uniformly rusty brown.

Microscopic examination showed what was evidently a cryptorchid testis, with extensive degeneration of the seminiferous tubules but with a rather remarkable increase of the interstitial cells (figs 6 and 7). There was no trace of ovarian elements. Because of the obviously testicular character of the gonad, in spite of the dominantly female characters of the patient, it was considered advisable to remove the testes. This was very simply done by ligation of the pedicles, with peritonealization of the stumps. Finally, the hypertrophied clitoris was excised.

Comment—The diagnosis as to the gonadally male sex of the patient was confirmed by further microscopic studies of many blocks from both gonads, all showing the features mentioned. Incidentally, the degeneration of the seminiferous epithelium is quite characteristic of the cryptorchid testis, and hypertrophy of the interstitial elements has likewise frequently been noted, some looking on this as important evidence that it is these elements which are responsible for the internal secretory function of the gland. The typical nature of the epididymis is well shown in figure 8.

In spite of the microscopic characters of the gonad, there seemed to be no question whatever that the patient should be allowed to continue life as a female. Aside from her dominantly female characters and her female psychology, the external genitalia were of the normal feminine type except for the overgrown clitoris and the rudimentary vagina. Clitoridectomy left only the vaginal defect to be dealt with, though this has been deferred for the present, at least until the patient has had a chance to recover her physical and mental equilibrium. Certainly, however, it would seem absurd in such a case as this to try to adapt the external genitalia for male purposes, even were this technically possible aside from the tremendous psychic upheaval that such an attempt would have inevitably entailed.

Subsequent Course—Much of the postoperative treatment was along psychological lines, as it should always be in such cases, with the object of reassuring the patient and making her feel that she could lead an essentially normal female life. There

seemed no advantage, and possibly much disadvantage, in having her know the masculine character of the gonads that had been removed. In the light of what has recently been learned as to the possibility of even the male gonad producing the female sex hormone, it is not certain that the removal of the testes served any useful physiologic purpose, though the natural reaction would be to look on their presence in such an individual as a "contaminating" male factor.

There were no menopausal symptoms after operation but the patient has been given preparations of the estrogenic

Fig 1—The patient by the side of a nurse of average height. The hypertrichosis is not shown in this picture as the patient had been shaved preparatory to operation.

substance from time to time since then. She reports that there has been only slight development of the breasts, but her general attitude toward life has been immeasurably improved. Life certainly has a different and more open-eyed outlook than it did a year ago. She says in a recent letter: "That her instincts are still highly feminine is indicated by another excerpt viz: 'Every normal desire a woman ever had is doubly strong in me now. Naturally, the fact that I can never have my own children is probably the most poignant and the greatest disappointment of my life.'

COMMENT

In discussing this unusual case, I shall devote little time to reviewing the extensive literature of hermaphroditism and its treatment. Until recently this literature has consisted largely of the reports of cases illustrating various incongruities and interminglings of internal

or external sex characters, often quite bizarre. No less than 1,891 such cases, observed up to 1908, were collected by von Neugebauer¹ in his monumental work "Hermaphroditismus beim Menschen." Many of the reports, too, have dealt with the problem of treatment and many ingenious surgical procedures have been performed in an effort to adapt the sex apparatus as nearly as possible to that of the sex to which the patient has been assigned, sometimes rightly, sometimes wrongly. The tremendous importance to the patient of making the right decision and the fact that this is not always dependent on gonadal characteristics were stressed by many writers even before much was known concerning the biology of the sex problem. The surgical treatment usually indicated involving as it so often does plastic procedures of delicate nature is obviously of the greatest importance to the patient. But the most interesting aspect of the whole problem it seems to me is the biologic one and it is highly desirable that all human cases of intersexuality be evaluated in accordance with the newer knowledge that is being obtained by biologists, geneticists and endocrinologists. At any rate it is with this aspect of the problem that the present paper concerns itself.

No intelligent discussion of the subject is possible unless one is familiar, in at least an elementary way, with the present day views as to the factors concerned in sex determination and sex differentiation. With reference to the first, there is a general acceptance of the view that it is the chromosomal make-up of the germ cells, and particularly that of the male, which determines whether the fertilized egg or zygote is to start out along male or female lines. The grouping of the chromosomes which in the human cell number forty-eight, differs in the two sexes. In both there are twenty-three pairs of autosomes (general body chromosomes), but it is in the remaining pair that the chief sex-determining function lies, and it is in these that the ovum and the spermatozoon differ. In the former this sex pair of chromosomes is made up of two so-called X units, so that the XX combination is the characteristic one for the female. In the spermatozoa, however, this pair of chromosomes consists of an X unit and a black sheep, the so-called Y chromosome.

In each cell, as is well known, fertilization is preceded by a halving of the number of chromosomes through the agency of a reduction mitosis. In this way the fertilized ovum will again contain not $48 + 48$ but $24 + 24$ chromosomes, this being the number characteristic of the human cell. As will be seen from the accompanying diagram (fig 9), each half of the female chromosome group will contain twenty-three autosomes and an X chromosome while on the other hand the two male halves will be dissimilar, one type of spermatozoon containing the X, the other the Y chromosome. The former type, fertilizing either of the female halves, produces a zygote with the double X combination, i.e., a female. The Y-containing spermatozoa, on the other hand, bring about the XY combination, which determines maleness in the zygote.

This, at any rate appears to be the mechanism of sex determination in the human being though vari-

Fig 2—The external genitalia showing especially the large clitoris. The inset shows a longitudinal section of the short rudimentary vagina.

ations of one sort or another characterize the process in other animal forms. For example, the oddness of one pair of chromosomes in the male cell may be indicated by the entire absence of one of this pair instead of by the presence of a Y chromosome. In certain lower forms, again, it is the female instead of the male cell that determines zygotic sex by its possession of an atypical sex-determining chromosome. This elementary description, however, is intended only to emphasize, in the simplest possible fashion that the initial sex-

¹ Von Neugebauer, F. L. *Hermaphroditismus beim Menschen*. Leipzig: Dr. Werner Klinkhardt, 1908.

determining impulse originates at the moment of fertilization and that it emanates from the germ cells themselves. How its sex-determining influence is impressed on the cells of the soma, all of which have the chromosomal make-up characteristic of the sex, is not known, though more and more evidence seems to be accruing that it is brought about by modifications of cell metabolism.

Fig. 3—Appearance of pelvis at operation showing no generative organs except the gonads (testes)

The determination of maleness or femaleness in the zygote, however, does not mean that the sex direction is purely male or purely female, for, as a matter of fact there is inevitably an admixture of the opposite influence. This, it is believed, may be due to the fact that the heterologous sex character present in the germ cell before maturation has already impressed itself on the cytoplasm. To put it another way, every zygote is bisexual, though the characters of one sex dominate and those of the other are submerged. This bisexual potency is carried through life, and its results are illustrated in the occurrence of organs and tissues, which are exactly homologous in the two sexes. For example, every woman has a potential testis in the rete ovarii; every man has a potential uterus (the uterus masculinus in the floor of the prostatic urethra), the woman has a vas deferens (Gartner's duct), and so on. Most biologists accept Goldschmidt's view that there is a quantitative balance or valence between the male and the female sex tendencies and that this balance can be overturned at a certain point (drempunkt), with sex reversal as a result. This is a crude summation of an extremely abstruse subject, but it will serve as a working basis for the purpose of this paper.

It would be confusing to elaborate on the conflicting theories concerning many aspects of the problem. Nor would it be worth while speculating on the mechanism whereby the chromosomal influence operates in unfolding the male or female development of the endocrine glands, especially the gonads. It is the latter which, in the human being, take over the dominant role in the unfolding of the secondary sex characteristics. It seems probable that the genetic balance is the dominating one

in the early phases of development but that later its influence is lessened, while that of the endocrine glands becomes correspondingly more important.

In certain lower forms, such as some of the insects, the initial impulse imparted by the chromosomal pattern is the all important one, determining quite inflexibly the sex characters of the animal. In the higher forms, including the human being, the initial impulse can, as already stated, be modified or even reversed by other factors that may become operative in later development, so that the sex characters may be profoundly modified or even reversed. The most important factor in such modifications of the genotypic impulse, and the one with which a consideration of the human problem especially must concern itself, revolves about the endocrine system. In the case of the insects, as already mentioned, both the sex determination and the differentiation of sex characters are purely chromosomal in origin, for there is no endocrine apparatus in such animal forms. In the higher animals, however, the ductless gland system assumes an auxiliary role of great importance in the molding of sex characters, so that the problem of the relative importance of the initial chromosomal impulse and the endocrine glands has become a very complicated one, and one whose explanation still baffles biologists.

What evidence is there for the role of the endocrines in modifying the original sex direction of zygotic development? Innumerable examples of the importance of the endocrines in this respect have been demonstrated by biologists. Perhaps most impressive of these is to be found in the classic studies of Lillie³ on the so-called freemartin. In cases of twin pregnancy in cattle, in which one fetus is genetically a male and the other a female, it often happens that the female at birth is found to show striking evidence of intersexuality, constituting the form to which the term "freemartin" is now universally applied (the German "zwickel"). The explanation of this phenomenon, as Lillie has shown, lies in the fact that at an early phase of development the two chorionic circulations anasto-

Fig. 4—Gross appearance of testes removed at operation. Note the attached epididymis on each side.

mose quite freely, so that the female is subjected to the influence of the male sex hormone, with the production of intersexual phenomena. These affect both the external and the internal genitalia, while even the female gonad may undergo testis-like transformation. Moreover, the "freemartin" is always sterile.

A similar influence of the gonads on sex characters has been demonstrated by Lipschutz⁴ in the case of mice and rats. Even more striking are the observations

made on birds by Crew⁵ and others. In hens, for example there is only one active gonad, the other remaining latent and rudimentary. In the well known case of Crew a hen in which the active left gonad had been destroyed by tuberculosis grew spurs and a comb, being both physically and behavioristically converted into a rooster. Although the animal had been the mother of a number of chicks, it now became the father of others. Autopsy in such cases shows the destruction of the hitherto active female gonad, in

Fig. 5—Cut surface of testis and epididymis. The former was reddish brown and of pulpy consistency.

Crew's case by tuberculosis, while the rudimentary right gonad shows striking development along testicular lines, with even actual spermatogenesis.

Similar instances of the reversibility of sex in fish, amphibian reptiles and other species are known to all biologists, the common frog furnishing a classic example of this reversibility under different environmental conditions, because of the fact that it possesses what is essentially an ovotesticular gonad. This, at any rate, is the interpretation commonly accepted as to the presence of the "Bidder's organ" associated with the gonad proper. For a discussion of this subject, and of other instances of sex reversibility in the lower species, the reader may be referred to the work on "Sex and the Internal Secretions" edited by Allen,⁶ and especially to the chapters of Danforth and Witschi.

Even as regards the human being, however, there is no lack of evidence as to the influence of the endocrines on the secondary sex characters. In this connection impressions are necessarily loose and superficial, because of ignorance of the mechanisms involved. For example, there is a tendency to look on hirsutism as an evidence of masculinity or arrhenoidism, a term suggested many years ago by Brant. At times this is unquestionably true as when it is associated with other arrhenoid characteristics such as flatness of the breasts, a muscular angular figure or a deep voice. On the other hand every clinician is familiar with the fact that extensive hypertrichosis, involving the face, extremities, thorax and abdomen, may be seen in women who otherwise seem normally feminine who menstruate normally, and who often bear many children.

Various endocrinopathies have been held responsible for this abnormality, especially the gonads, the adrenal cortex, the pituitary and the pineal body. When our

knowledge is increased it will probably be shown that the interrelationships of the glands are responsible for this apparently multiple etiology and that the seat of the disturbance can be narrowed down much more sharply. The evidence to date would seem to indicate that the adrenal cortex is to be suspected most strongly in this connection. That it actually is at fault in some cases is shown by the well known association of hirsutism with cortical tumors and other lesions. Unfortunately, even profound phenomena may be due to lesions, usually adenomas, so tiny as to be beyond recognition by any clinical or laboratory method now available. Cushing has shown the frequent coexistence of small anterior pituitary and cortical adenomas with the syndrome that he ascribes to basophilic pituitary adenoma. Hypertrichosis is not always present in the Cushing syndrome, and I know of no evidence to indicate that its presence is linked up with the adrenal adenomas that have been found in a number of these cases. A lot more will have to be learned about hypophyseocortical relationships before one can even speculate intelligently, but the recent report of Walters⁷ indicates that at least some cases of extensive hypertrichosis may be treated surgically, by removal of cortical lesions.

Just why hirsutism is at times so extensive in women with no definitely intersexual manifestations, and why, on the other hand, it may be slight or absent in some cases of marked intersexuality, cannot be explained, though this fact makes one question the significance of hairy overgrowth per se as a manifestation of abnormality in sex differentiation. With reference to such changes as marked regression of the breasts the problem seems different, for here one is dealing with a manifestation of defeminization, while with such manifestations as overgrowth of the clitoris one may assume a positive masculinization. If the views held by many as to the antagonism of the sex hormones are correct, this may be a distinction without much difference, but the evidence on this point is far from complete.

Fig. 6—Microscopic appearance of removed gonads showing in this area fairly well preserved seminiferous tubules. Note the marked increase of interstitial cell elements.

When one has to deal with actual anatomic manifestations of intersexuality in the external and internal organs of generation, there would seem to be little question that the underlying disturbance involves the mechanism that normally governs the differentiation of the two sexes. All grades of intersex have been described and usually with a sharpness of classification.

that the slowly growing knowledge of the subject does not appear to justify. The division into true hermaphroditism and pseudohermaphroditism may be convenient, as may be the subdivision of pseudohermaphrodites into groups according to the juxtaposed characters of the gonads and the internal and external genitalia according to the plan originally suggested by Klebs and still widely employed. Biologists, however, are beginning to look on such classifications as artificial and obsolete, urging that they represent merely grades of intersexuality produced by quantitative sex imbalance.

This is well illustrated in the case of true hermaphroditism. In its strictest sense this term would indicate the production in the same individual of both female and male germ cells (ova and spermatozoa), and in this sense no human case has ever been described. The more common plan has been to designate as true hermaphrodites individuals possessing both male and female gonadal tissue, but a moment's reflection will convince one of the incorrectness and uselessness of such a criterion. In the first place almost all the reported cases of this group have been characterized by the presence of ovarian and testicular tissues in the same gonad, the so-called ovariotestis. In some of these it is probable, and in some of them quite certain, that the testicular portion is to be interpreted as a pathologic new growth developing in the rete region of the ovary of an individual who is genetically a female. This is undoubtedly true in the case of Polano⁸ originally reported as a true hermaphrodite and certainly belonging to this group if the possession of gonadal tissue of both sexes is accepted as a criterion. In this case, however, as Meyer has shown the testicular elements are neoplastic, constituting the so-called testicular adenoma originally described by Pick. In Blair Bell's⁹ case, also described as an unquestionable instance of true hermaphroditism, the gonad can now be readily interpreted as an ovary in which there has

As a matter of fact, there have been a considerable number of cases reported in which the only gonads possessed by the patient have been testes and in which nevertheless, the external sex characters of the patients have been typically feminine. My own case belongs to this group, as does a second case reported by Blair Bell⁹ as having been observed by Russell Andrews. In this group are also to be placed the cases reported by

Fig 8—Microscopic appearance of epididymis

Prince,¹⁰ Jordan,¹¹ Halban,^{2b} Cadiz and Lipschütz,¹² Wagner,¹³ and Guggisberg.¹⁴

Emphasis may again be placed on the sex-modifying capacities shown by certain tumors of the ovary to which attention has been called in recent years, chiefly through the studies of Robert Meyer.¹⁵ One of these the granulosa cell carcinoma, secretes the female sex hormone so that if it occurs in children it brings about precocious puberty and menstruation while in old women it may cause an apparent reestablishment of menstruation, perhaps many years after the menopause. With this feminizing tumor the present paper is not concerned.

By contrast, the arrhenoblastoma produces the testis hormone, so that especially in its more undifferentiated forms it may bring about striking masculinization of sex characters, such as hirsutism, deepening of the voice, atrophy of the breasts, amenorrhea and enlargement of the clitoris to even penis-like proportions. As the removal of the tumor is followed by a complete or partial disappearance of these phenomena, these tumors offer a striking illustration of the ability of the hormones to influence the secondary sex characters. As I have discussed this group of tumors elsewhere,¹⁶ I shall not elaborate further in this paper. It is not amiss however to point out the close embryologic relationship between the adrenal cortex and the ovarian medulla so that it is not surprising that there is a close similarity in the masculinization syndromes produced by tumors of these two structures.

No consideration of this subject would be complete if it did not include at least a brief reference to the

Fig 7—Another area showing degenerated tubules

developed an arrhenoblastoma, the cells of which possess the capacity of secreting the testis hormone and thereby bringing about a greater or less degree of masculinization. An analysis of these and other cases tends to weaken one's faith in the value of the aforementioned criterion of true hermaphroditism and to convince one that the underlying factor lies deeper than this.

recent epoch-making studies on the chemistry of the male and female sex hormones. The molecular structures of both ovarian hormones (estrin and progesterin) and also of the male hormone have apparently been established, the remarkable feature being that all three of these substances are chemically so closely related that they may well be looked on as derivatives of one another. All three of them exhibit the same phenanthrene nucleus, and this same three-membered hexagonal ring characterizes certain well known chemicals of the sterol group, the bile acids, certain vitamin principles, and the carcinogenic substances that have long been known to be capable of producing skin cancer in experimental animals. With the latter aspect of the question, perhaps the most suggestive of all this paper is not concerned, though the interested reader will find it authoritatively discussed in the recent paper of Loeb.¹⁷

The intimate chemical kinship of all the sex hormones, however, may prove to be very pertinent to the question of sex differentiation. It has long been known that the urine of some men contains the female sex hormone, while on the other hand the finding of the male hormone in the urine of women during the reproductive phase of life seems quite constant, according to the careful studies of Siebke¹⁸ and others. There are quite a number of experimental studies, too, to indicate an apparent facultativeness in sex hormone effects. Laqueur and Fellner, for instance, have produced definite estrous effects, as determined by the vaginal smear method, by means of testicular extracts, while masculinization effects have been produced by means of corpus luteum extract (Steinach and Kun). Cadiz and Lipschütz¹² noted typical and pronounced vasomotor menopausal symptoms after removal of the testes from an intersexual patient who, like my own, exhibited dominantly female body characteristics though no ovarian tissue was present. I have myself seen typical vasomotor flushes and sweats in a male castrate. And the examples might be multiplied.

Evidence of this kind rather than indicating mild degrees of intersexuality, supports the growing view that the cells of either sex type of gonad are capable under different conditions of producing either male or female sex hormone. This question is closely related to the view championed by Witschi⁹ and accepted by many biologists that the male or female character of the germ cell is determined by whether it develops in the medulla or the cortex of the gonad. To put it another way, the cortex is a determiner of femaleness, the medulla of maleness. That this is true in the case of the frog has been established by abundant experimental evidence. If there is such a facultativeness as regards the germ cells, it would not be surprising if there should also be an environmental influence on the character of the sex hormones. It is easy to see too why the present hormone studies on the blood and urine of intersexual patients cannot be expected to yield decisive information as to the real or genetic sex of these individuals.

After all every intersex is primarily male or female and in the case of the human being at least practically always female. The so-called true hermaphrodite, commonly looked on as the acme of intersexuality because of the possession of both male and female gonadal tissue, represents as a matter of fact a lesser degree of intersexuality than some individuals with only one type of gonadal tissue who are by common usage spoken

of as mere 'pseudohermaphrodites'. The justification for this statement as regards certain lower animals is quite clear from the evidence already in hand, and there can be little doubt that, though obviously difficult of proof, the same thing applies to human intersexuals also.

If this assumption is correct, such patients as the one I have described and others of similar nature represent genetic females in which the sex reversal took place at very early phases of development, with complete replacement of ovarian by testicular elements. Depending on the time and intensity of the sex switch, all sorts of intergrades may develop, including perhaps one in which both ovarian and testicular tissue are still present. The secondary sex characters constitute a mosaic that reflects these changes occurring in the endocrine glands, though too little is known of pathways and time relationships to permit of any accurate interpretation of the disturbances underlying these abnormalities.

SUMMARY

The prime purpose in this paper is to apply to the study of human intersexuality the newer biologic knowledge concerning sex determination and sex differentiation. Some of these new principles must materially alter the interpretation of many cases of intersexuality. To take the most extreme example, true hermaphroditism in which both ovarian and testicular

Fig. 9—Chromosomal pattern of male and female germ cells and manner in which sex is determined according to type of spermatozoon that fertilizes ovum (see text).

tissue is present in the same patient, has been commonly thought to represent the maximum grade of intersexuality. As a matter of fact, a certain group of these patients are females in whom there has developed in the region of the rete ovarii a testicular type of tumor, of either the differentiated or the undifferentiated type (arrhenoblastoma). Other cases of "true" hermaphroditism are to be interpreted as representing a less complete sex reversal than is seen in such instances as the one I have reported in this paper, in which an individual who is genotypically a female exhibits only testicular gonadal tissue so that she would technically be classified as a masculine pseudohermaphrodite. These cases are perhaps explainable on the same basis as the cases of sex reversal seen in certain lower animals, though the proof of this is not yet available.

The two great forces in determining the sex development of the individual are, first, the initial germinal impulse dependent on the chromosomal pattern of the zygote and second the endocrine glands. The former factor is presumably dependent on a quantitative balance between the male and the female elements of an always bisexual cell and this balance is capable of partial or complete reversal by abnormalities in the endocrine system with the production of sex intergrades of one sort or another. The chromosomal impulse is probably most important in the early phases of sex differentiation, the endocrine system in the later stages. The

character and degree of intersexual phenomena depend largely on the phase of development at which the sex switch occurs

26 East Preston Street

ABSTRACT OF DISCUSSION

DR ELIAS P LYON Minneapolis Regarding the psychologic differences it occurred to me to ask whether the author thinks that these might not be environmental. This person was raised as a girl. A hotmist has told me that somebody has recently discovered some form of fungus in which there appear to be four sexes. Two sexes are accepted as something that is natural and inevitable. He says that the phenomena of human intersexuality can be explained only by thinking of four sexes.

DR P M MENLOWE McKeesport Pa There is a patient in a hospital in McKeesport in whom sex peculiarities were noted when he was admitted following a railroad accident. His latest vocation was apparently that of a freak in a circus side-show. He was born twenty nine years ago in Russia. At the age of 8 years he was brought to this country and was dressed as a girl until the age of 19 sleeping with his stepsisters. He then became a nurse at one of the local eastern hospitals. The following year he became ill and a gynecologist who examined him told him that he was a male and that it was probably best that he dress as one. He subsequently accepted odd jobs all over the country leaving each place as soon as the people he worked for noticed that he had peculiarities. Recently he had been receiving testicular treatments. His body lends itself to either male or female attire. In wearing men's clothing he says that he feels fairly comfortable. There is no feeling of awkwardness about him. He says that as a child he preferred to play with boys rather than girls toys. He says he has been able to participate in intercourse giving pleasure both to himself and to his partner. He has a delicate skin and face and thick long brown hair but no widening of the pelvis. The distribution of hair over the pubis is definitely feminine. The clitoris as he calls it looks like a small atrophied penis. There is no urethral opening in the penis. Below the penis two testicles show definitely. The cleft is very small. In the space below the penis but independent of it are three openings and he does not know from which one urine is voided. Below this is another large opening which admits the tip of the small finger. He does not menstruate and he does not care for feminine attire.

DR JACOB AUSLANDER New York Were any of the quantitative tests used such as those outlined by Dr Robert T. Frank e. g., the quantitative assay of estrogenic substance in the blood? Dr Frank has repeatedly described the technique of this method by which it can be definitely established whether ovulation takes place in a particular person and whether or not any functioning ovarian tissue is present. I believe that this method is invaluable in determining the sex in doubtful cases.

DR EMIL NOVAK Baltimore I think it unlikely that the female psychology of this patient was due to environmental influences. In many cases of intersexuality the psychology develops along sex lines directly opposed to what might be expected from environmental conditions. Furthermore in some fairly similar cases the removal of the testes has produced typical vasomotor menopausal symptoms indicating the presence of an endocrine rather than an environmental influence. Unfortunately it is not possible as yet to determine the genetic sex of an intersexual person by a study of the chromosomes in the body cells. Nor does the demonstration of the sex hormones help in this respect, as Dr Auslander suggests. Aside from the possible facultativeness of the gonads and hormones it is now well known that the male hormone is commonly found in the urine of women and the female hormone in the urine of some men. The case described by Dr Menlowe seems to belong to the category of masculine pseudohermaphroditism, of which there are many gradations. Little enough is known about the whole problem and further knowledge can be obtained only by studying human cases from the biologic rather than the merely anatomic standpoint and by utilizing such knowledge as scientists are gradually accumulating.

THE BALANITIDES

JOHN F. MADDEN, M.D.

ST. PAUL

The balanitides are inflammations of the glans penis that are usually associated with inflammations of the prepuce. A classification of the balanitides should be made on a bacteriologic, anatomic, histopathologic and clinical basis.

CLASSIFICATION

- 1 Balanitis simplex
- 2 Balanitis vulgaris
- 3 Balanitis due to specific local infections
- 4 Balanitis as a part of general exanthematic diseases
- 5 Balanitis accompanying metabolic disorders
- 6 Balanitis accompanying new growths
- 7 Balanitis following local tissue changes

BALANITIS SIMPLEX

Balanitis often occurs as a complication in various forms of congenital and acquired phimosis. Infants and small boys may have an adherence of the prepuce to the glans, which produces a pseudophimosis. When this adhesion is loosened manually, a slight secretion is formed, which has its basis partially in the liquefaction of the connecting cell layer. This secretion can also be produced by the mechanical irritation caused by the bridge-like connections between the two sheaths of the prepuce or by the action as foreign bodies of the epithelial cords remaining at the junction of the prepuce and glans. The constant irritation of the secretion plus mechanical factors lead to a true phimosis and balanitis.

Atrophic and hypertrophic congenital phimosis of the adult promote the occurrence of balanitis. Many people with atrophic congenital phimosis never have balanitis, especially when the urethral orifice lies opposite the opening in the prepuce and urine does not accumulate in the foreskin sac. However, distress is experienced during coitus and marginal tears may result which increase the chances of getting syphilitic and other infections. The hypertrophic form causes frequent retention of urine within the prepuce. This results in chronic irritation, in thickening of the epithelium and often in leukoplakia. Smegma accumulates in greater amounts, bacteria grow more rapidly, and the erosions which often form may heal with such extensive adhesions that the entire prepuce may become adherent to the glans.

Balanitis can occur as a complication of acquired phimosis. In these cases the phimosis is primary, and the balanitis appears usually after repeated long standing or very severe phimosis. External chemical agents, pediculi, urticaria, Quincke's edema, erysipelas, elephantiasis of the genitalia as the result of inflammatory changes in the inguinal lymph glands, cancer, freezing, tuberculosis, actinomycosis and cardiorenal disease can all cause edema of the prepuce and phimosis that result in balanitis. Hoffman² described a case of xanthomatosis in which the presence of xanthomatous deposits in the prepuce caused edema,

Owing to lack of space this article is abbreviated in THIS JOURNAL. The complete article appears in the author's reprints from the Division of Dermatology and Syphilology, University of Minnesota Medical School, Dr. H. E. Michelson, director. Read before the Section on Dermatology and Syphilology at the Eighty-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., June 13, 1935.
² Hoffman, G. Balanitis. Handb. d. Haut u. Geschlechtskr. 21: 324, 1927.

phimosis and finally balanitis. In all of these the phimosis is acquired primarily and the balanitis secondarily.

BALANITIS VULGARIS

There is a large group of the balanitides which is clinically characteristic but the bacteriology of which is not completely understood. This type may be called balanitis vulgaris. The causes are trauma, chemicals or bacteria, and all may produce a diffuse inflammation of the preputium.

Traumatic balanitis is the result of mechanical irritation such as is commonly produced by tears and rarely by preputial stones. The bacteria are usually the same as in the normal preputium.

Chemical balanitis sometimes results from the use of certain chemicals in antiseptic washes, compresses or urethral injections. Corrosive mercuric chloride in strong solutions, phenol and compound solution of cresol produce a diffuse, painful, weeping or blistering balanitis. Iodoform can cause a severe eczematous eruption. Cordier¹ found that iodine preparations given internally with simultaneous application of mild mercurous chloride into the preputium could produce a very painful diffuse balanitis, which he thought was brought about by yellow mercurous iodide arising from the combination of mercury with iodine. Mercury used locally in any form may produce a severe reaction. Certain drugs such as cantharides, sodium nitrate and sodium iodide taken internally occasionally cause balanitis. Schreus² demonstrated that intramuscular injections of bismuth compounds sometimes produce an inflammation of the glans similar to erosive balanitis. He showed that the dark color of the smegma in these cases was due to the deposit and excretion of bismuth sulphide. This finding in the glans corresponds to bismuth deposits with occasional gingivitis in the mouth. Certain plants and powders from plants, such as the so-called itch powder made from a plant grown in the West Indies, have been known to cause inflammation of the preputium. The frequently seen postcoital balanitis has been regarded by many as only an irritation caused by vaginal secretion. Von Bokay³ observed and described a form of balanitis seen in boys from 1 to 13 years of age, which appears first around the urethral orifice as a lentil sized inflammation with a lardaceous surface and infiltrated base. The lesion spreads and becomes ulcerous and the urethral meatus is held together by crusts. The urine is clear and normal and there is no inguinal adenitis. The balanitis is caused by chemical irritation produced by ammoniacal fermentation of the urine. This eruption is seen in children who lie for long periods in wet diapers, in older children who are troubled with enuresis, or in adults who are incontinent for a long period.

Under bacterial causes of vulgar balanitis are many of those forms of balanitis which recur frequently without apparent cause. They may be explained by an irritation of the preputium caused by an increased secretion of pathologically changed smegma. However, Tommasoli⁴ and others consider this type analogous to seborrheic eruption in other locations. Finger⁵

believed that under normal conditions certain people produced a thin smegma which acted as an irritant alone. Others thought that bacterial investigations showed that certain bacteria act as decomposers of smegma and that this action may cause balanitis. These patients produce a thin smegma associated with an itchy balanitis, which recurs from time to time. The eruption promptly disappears under proper hygienic measures and any mild treatment. A diffuse catarrhal balanitis is described in which the entire foreskin sac is involved, with or without erosions, a thin yellowish gray pus develops, and pseudodiphtheria bacilli are found in enormous numbers. This may be associated with balanitis caused by *Oidium albicans*. Benedek⁶ called the eruption balanoposthitis *oidiomycotica* and described a case. Scherber noted a form of balanitis occurring after coitus with menstruating women and recorded four cases. The patients were married, and they had frequent recurrences of balanitis after intercourse with the menstruating wife. The eruption appeared as a diffuse red inflammation with simultaneous formation of numerous pustules the size of a millet seed or larger. He thought that the irritation was from the menstrual secretion and that the pustule formation was secondary. The so-called pustulo-ulcerous balanitis of du Castel is said to begin in the sulcus coronarius following sexual intercourse. It appears in the form of yellow pustules as large as a millet seed, from which polycyclic, diphtheritic coated ulcers develop. The pustules burst and heal in a few days or the healing is slower when ulcers are formed. Pautrier and Rietman⁷ and Levy-Bing and Gerbay¹⁰ are among the few who have reported similar cases.

BALANITIS DUE TO SPECIFIC LOCAL INFECTIONS

Erosive balanitis is an acute inflammatory disease of the prepuce and glans penis caused by Vincent's spirochetes and fusiform bacilli in symbiotic relationship. The infection was first described by Bataille and Berdal¹¹ in 1891 and later by Pusey,¹² Corbus¹³ and others. It is far more common in males, but a similar eruption has been noted by several observers in females. The disease practically never occurs under aerobic conditions. The organisms are strictly anaerobic and their growth is promoted by phimosis, a long tight foreskin, heat, uncleanness, moisture and lack of air. The condition is not seen in paraphimosis or in patients who have been circumcised. Jefferson,¹⁴ Corbus and others thought that lubricating the labia or glans penis with saliva and the practice of coitus oris were contributing factors in producing the disease. It has been shown that fusiform bacilli and Vincent's spirochetes are saprophytic inhabitants of some preputial sacs.

I agree with Brams and Pilot¹⁵ that erosive balanitis need not be venereal in origin but that under suitable local conditions, often associated with lowered general

resistance or poor personal hygiene, erosive balanitis may result from the organisms normally present as saprophytes. The patient shown in figure 1 had not had coitus for several weeks before the balanitis developed. Erosive balanitis is seldom accompanied by subjective symptoms. The epithelium becomes necrotic and the lesions soon appear as gray or white necrotic erosions on the foreskin and glans. The central part of the necrotic slough is cast off leaving a red, superficial erosion with a necrotic border. There is an associated swelling, phimosis and edema of the prepuce and glans. The erosions enlarge peripherally soon become confluent and form circinate lesions with polycyclic borders. These changes are accompanied by the formation of very foul smelling pus, which is thin yellow and abundant and increases as the eruption develops. Erosive balanitis is auto-inoculable and inoculable from patient to patient. For this reason many authors have included it among the venereal diseases.

Now and then erosive balanitis or condylomata acuminata may prepare the ground for each other and they are not infrequently seen together.

short time. The discharge is more serosanguineous than in erosive balanitis. The eruption is always very painful and is generally associated with complete phimosis.

Ulcerating, gangrenous balanitis with phagedena represents a more virulent process than gangrenous balanitis. The two types are clinically similar and histologically the same, varying only in the intensity of the inflammation present. In gangrenous balanitis with phagedena the resistance of the patient seems to play the major role in determining whether the infection will stop. Matzenauer¹⁶ described the first case in 1901 and other cases were reported before 1928, when Labadie¹⁷ published in account of several cases seen at the University of Michigan. The ulcers are similar to those seen in gangrenous balanitis when they first appear, but they spread rapidly in circumference and depth. The lesions are sharply margined, very painful and covered with a firm, necrotic, brown to black, adherent gangrenous membrane. A severe phimosis, a foul, abundant secretion, and edema of the entire penis almost always accompany the ulceration. The eruption spreads by direct extension over the genitalia and may

Fig. 1—Erosive balanitis

Fig. 2—Diffuse balanitis arising from a macular roseola in secondary syphilis

Fig. 3—Erythroplasia of Queyrat before malignant changes have appeared

Gangrenous balanitis and erosive balanitis are caused by the same organisms. However, gangrenous balanitis presents a fulminating, rapidly progressive infection with severe subjective symptoms. It occasionally results from an untreated, improperly treated or undiagnosed case of erosive balanitis, but the erosive symptoms may be entirely absent because they are passed through very rapidly. Gangrenous balanitis begins on the inner surface of the foreskin, usually near the sulcus coronarius, as small, round erosions covered with a grayish white diphtheritic membrane. The erosions enlarge rapidly, coalesce, break down and form ulcers. The ulcers extend in depth and circumference and are covered by a black, gangrenous membrane. The border is sharply margined and angry red, while the base is uneven and granular. There is an inflammatory halo of varying degrees of intensity around the ulcers. The process is much more intense and rapid than in erosive balanitis. The ulcers can form and perforate the foreskin in a few hours. Here they show through the prepuce first as dark red patches, later the color changes to black, and then the entire preputial area becomes necrotic and sloughs, and the glans shows through the opening. If the ulcers are on the glans, severe hemorrhages may occur and the entire glans may be destroyed within a

involve the abdominal wall, thighs and surrounding skin. The prognosis is poor, and many cases terminate in death. The condition can progress, no matter what type of early treatment is used.

Ulcerating, gangrenous balanitis with phagedena, gangrenous balanitis and erosive balanitis are all different clinical varieties of the same etiologic, pathologic and histologic process, which differs only in the severity of the infection.

Balanitis in gonorrhea occurs in the acute cases commonly but is rarely seen in chronic gonorrhea. There are cases of balanitis caused by direct deposits of gonococci in the crypts, sebaceous glands, and para-urethral passages. The balanitis develops in part through the effect on the epithelium of gonococci, which have come through the blood or lymph channels into the subepithelial connective tissue of the glans and foreskin. Baermann¹⁸ described balanitis circinata gonorrhoeica as numerous, round, red lesions which had a wet sheen, do not excrete and are surrounded by a

narrow corona of delicate whitish epidermal scales. Many efflorescences are completely covered by a dry, crumblike grayish yellow coating or horny shield. These lesions can coalesce to make wreathlike figures. Histologically the tissues show acute inflammation, the rete layers are chiefly affected and a temporary vesicular stage may precede the crusts and scales. Gonorrhea can also cause the following types of balanitis: balanitis circinata hypertrophicus found in a case of blennorrhagic keratosis by Haslund,¹⁹ gonorrheal follicular abscesses on the inner sheath of the prepuce,²⁰ and gonorrheal balanitis with complete phimosis but without urethritis.²¹

Balanitis caused by the diphtheria bacillus is a very rare condition although a case has been recently reported by Borovskiy.²² Infection of the female genitalia is seen more frequently. The disease can be transferred by hand from a pharyngeal diphtheria or it may arise by primary inoculation. A typical, extensive, grayish yellow, diphtheritic membrane is formed early. Crusts are formed which become loosened, drop off, and leave ulcers with irregular borders and bases covered with grayish white diphtheritic pus. Culture of the pus on Loeffler's serum shows true diphtheria bacilli. While diphtheria bacilli and Vincent's organisms have been found in the same mouth, no record was discovered of any other organism being found in a diphtheritic balanitis.

BALANITIS AS A PART OF EXANTHEMATIC DISEASES

Syphilis is the disease that most frequently produces this type of balanitis. The primary lesion of syphilis may take the form of a specific balanitis. So-called syphilis d'emblee in which a chancre is not observed and the first sign is a secondary eruption might be explained in some cases by the primary lesion appearing as a specific balanitis. Follmann²³ and others have recorded such cases. The primary manifestation of syphilis can appear as small, pinhead sized erosions covering the entire preputial sac. There is no induration or urethral discharge. The individual lesions are superficial, red and painless. Dark-field examination is always positive for *Spirochaeta pallida*. The erosions exude serum but pus is found only when secondary infection exists. The balanitis is accompanied by a typical, hard shotty discrete inguinal lymphadenitis. Microscopic examination of biopsy specimens shows the usual condition found in a chancre. Also the primary lesion may appear as a combustiform chancre in which the erosion covers the entire glans and prepuce. This lesion is accompanied by slight infiltration and *Spirochaeta pallida* is abundant.

Finger Kreibich²⁴ and others have described secondary syphilis manifesting itself as a balanitis. The lesions arise from a macular secondary roseola and appear as sharply circumscribed painless erosions which coalesce, exude serum and spread out over the glans and prepuce. The lesions may involute, become papular, or be complicated by erosive balanitis. When

phimosis exists, there usually is a diffuse balanitis such as seen in figure 2.

Many other exanthematic diseases such as pemphigus, psoriasis, erythema multiforme, lichen planus and scabies may show balanitis at some point in their course. Medicinal agents taken internally that produce exanthems rarely produce balanitis. Some of the rare examples that cause inflammation of the preputial sac are antipyrine, arsenic, quinine and iodine. Phenolphthalein on the other hand, commonly produces an erythema multiforme type of balanitis. It can also produce fixed eruptions, which appear on the glans as bluish red, fixed, itchy plaques of various sizes. The eruption subsides, becomes less itchy, and leaves a brownish discoloration between periods of ingestion of phenolphthalein.

BALANITIS ACCOMPANYING METABOLIC DISORDERS

Balanitis accompanying disturbances in metabolism can occur as the result of direct irritation by the urine or from substances contained in the urine. The balanitis may follow the retention of these substances within the foreskin sac, their excretion in large amounts, their chemical decomposition, or the production of a bacterial or vegetable growth that they promote. The excretion of large amounts of sugar, phosphates, creatinine, oxalates and urates in the urine and ammoniacal fermentation of the urine are some examples. The urine does not contain enough of these salts to produce a balanitis under normal conditions. Some salts, particularly phosphates and urates, form stones which produce balanitis when they are retained in the preputial sac. When large amounts of creatinine are excreted, ammoniacal fermentation accompanied by severe balanitis may be present.

Diabetic balanitis is the most common example of balanitis resulting from a metabolic disturbance and is present in some degree in about 7 per cent of all male diabetic patients. The eruption is usually caused by glycosuria, with retention of urine in the preputial sac and the development of a secondary mycotic dermatitis. However, balanitis has been known to appear when there is an increase only in the blood sugar and no demonstrable glycosuria. Fungi are always found in large amounts in the more marked cases and are generally conceded to be the direct cause of the balanitis. Monilia, *Aspergillus*²⁵ and *Oidium*²⁶ have been found. Cooper²⁷ emphasized that the slight bleeding from these fissures may be the only symptom of diabetes that causes the patient to consult a physician. When the eruption becomes more marked, proliferative vegetations may appear on the glans. These growths have an abundant blood supply and bleed on the slightest touch. Tuffier²⁸ saw cancer develop from such a papilloma. Ulcers may accompany or follow the numerous fissures, which appear at the foreskin opening. The ulcers are sharply margined, terraced, and covered with a whitish yellow membrane. After the ulcers heal the resulting scars are contractile and produce a rapid phimosis. The foreskin may become edematous, thick, rigid and immovable. Finally gangrene may develop. All cases are very obstinate and remissions and exacerbations are common over a long

period Any case is in constant danger of being complicated by gangrene or erysipelas

BALANITIS ACCOMPANYING NEW GROWTHS

Erythroplasia of Queyrat was recently introduced to the American literature by Sulzberger and Sitenstein²⁹ and Stiles³⁰ It is a precancerous dermatosis of unknown cause which can change over immediately

Fig. 4 (case 2)—Raised thick patches in leukoplakic balanitis

into cancer The eruption begins on the glans penis as lentil sized, moderately elevated, shining or intensely red plaques with an uneven velvet-like surface which secretes a varying amount of fluid The eruption can spread over the entire preputium The lesions are moderately firm may show a slight scale, and are often sensitive on pressure The clinical malignant change can be noted by thickening, infiltration and finally ulceration Microscopically in erythroplasia there is a very marked acanthosis which extends deep into the cutis in the form of finger shaped processes There is a moderate lymphocytic and plasma cell infiltrate in the cutis The change to cancer is difficult to detect because the epithelium which suddenly takes on malignant characteristics, is already deeply proliferated and ramified Erythroplasia, Bowen's disease and other precancerous dermatoses should be treated as cancer as soon as they are recognized Figure 3 is an example of erythroplasia before malignant changes have appeared

BALANITIS FOLLOWING LOCAL TISSUE CHANGES

There is a group of diseases which produce clinical pictures somewhat similar to one another but which are distinct clinical and pathologic entities In these diseases, local tissue changes occur from one cause or another and balanitis often results Kraurosis penis leukoplakia, scleroderma and balanitis xerotica obliterans are included under this general heading

It cannot be denied that kraurosis penis and leukoplakia are sometimes seen in the same patient, but, for the most part, the diseases occur separately Montgomery³¹ thought that kraurosis vulvae and leukoplakia of the vulva could be distinguished from each other on clinical and pathologic grounds, and I think that this observation holds true when the two diseases are considered in the preputium

Thibierge³² and Kraus³³ believe that kraurosis penis balanitis is similar to kraurosis vulvae in women The

eruption develops late in life, more often after 50 years of age Some observers thought the disease was associated with loss of sexual power and atrophy of the penis The first symptom may be severe pruritus which usually continues throughout the course of the disease The eruption may begin as a common balanitis as in case 1

CASE 1—*Kraurosis penis* M K, a man aged 71, a laborer, first noticed redness of the glans and prepuce accompanied by burning, itching and an increased secretion within the preputium about December 1932 The itching became more marked, and adhesions began to form between the foreskin and the glans about December 1933, and white, rough patches appeared on the glans On examination, Dec 31, 1934 the prepuce was adherent to the glans anterior to the sulcus coronarius The exposed surface of the glans was atrophic, pale and bluish white, and an occasional excoriation was visible On the left side of the glans, at the site of the adhesion of the prepuce to the glans was a hard, firm slightly painful, pea sized raised white papule which had been present for about one year and recently had begun to grow quite rapidly The lesion involved both the glans and the prepuce The patient was circumcised and the papular lesion removed by electrocautery The biopsy showed kraurosis penis with questionable early carcinoma at the site of the white papule.

Later the prepuce and glans show atrophy and a continued increase in the loss of elasticity, and a peculiar paleness of the tissue develops Deep furrows appear between the patches of eruption on the glans and prepuce Atrophy and sclerosis continue, and mechanically produced fissures and tears appear at the preputial margin Epithelioma, which usually appears in the sulcus coronarius in the late stages of kraurosis penis is generally of the squamous cell type Kraus summarized the microscopic changes as follows There is an acanthosis and hyperkeratosis with inflammatory changes in the connective tissue, which go over into atrophy of the epithelium and progressive atheromatosis of the vessels

Leukoplakia can occur in the preputium, and here it is identical with that seen in the mouth It almost always follows or is associated with some form of chronic irritation produced by surface irritants or inflammatory reactions in the cutis Diabetic, erosive and common balanitis on the surface frequently precede leukoplakia Infiltrates accompanying syphilis, which can remain in the cutis even after thorough antisyphilitic treatment favor the development of phimosis and chronic balanitis, which in turn often result in leukoplakia and cancer Leukoplakia is characterized by various sized patches, which show a thickening of the epithelium a white to bluish white color, a loss of some of the normal surface markings and a smooth, shining surface, which may be eroded here and there In some cases the surface is roughened and covered with papillary excres-

cences If the leukoplakic inflammation is severe or continues for some time, the external sheath of the preputium and the glans becomes very thick. The entire foreskin and glans may become rigid and stiff and show various degrees of loss of elasticity such as seen in case 2.

CASE 2—Leukoplakic balanitis. L. B. a laborer aged 45 noticed white spots appearing on the foreskin and glans penis about three years ago. These lesions increased in size and thickness until most of the prepuce and the anterior half of the glans were involved in one year. There were no subjective symptoms until about two years ago when the patient experienced discomfort and pain when he had an erection and during intercourse. The patient had no sign or history of syphilis, and the blood Wassermann test was negative. On examination in March 1935 the process involved the entire prepuce and glans. The frenum had been destroyed and the glans was bluish white, covered with thickened patches, rigid and slightly tender on palpation. The microscopic section revealed typical leukoplakia.

The microscopic changes show lymphocytic infiltration in the corium and hypertrophy of all layers of the epidermis. There is a marked hyperkeratosis, with patches of parakeratosis scattered throughout. The acanthosis is usually marked, and long, narrow rete pegs and papillae result. The blood vessels of the corium are dilated, and a perivascular lymphocytic infiltrate is found. Leukoplakic balanitis is a most dangerous eruption and should be destroyed as soon as possible. Often the patients do not consult a physician until cancer has developed.

The usual changes that occur in scleroderma on the skin are seen in a sclerodermic balanitis. Gougerot³⁴ recently reported two cases of this rare disease. The eruption develops insidiously, without subjective symptoms. Edema, inelasticity or stiffness is often the first sign to be noticed. The disease may involve the entire preputium. The edematous, tense, infiltrated inflammatory stage passes quickly. The characteristics of fully developed scleroderma soon appear and include an ivory whiteness, a lardaceous appearance, atrophy, induration, rigidity and binding down of the skin to deeper structures. The microscopic changes are characteristic of scleroderma and cannot be confused with that of other forms of balanitis in this group.

Balanitis xerotica obliterans is an entity closely related to kraurosis penis and scleroderma and was first formally described and named by Stühmer³⁵ in 1928. The condition was called to the attention of Dr. Michelson by Professor Oppenheim of Vienna before that time. Dr. Michelson has observed quite a number of cases and has given me the privilege of reporting several examples of this rare and characteristic condition. As far as I know, these cases are the first ones to be described and recorded except in the German literature.

CASE 3—*Balanitis xerotica obliterans*. H. G. aged 23 a private patient of Dr. Henry E. Michelson noticed two or three red spots on the glans penis in the fall of 1932. He said that the lesions looked like blood blisters. They grew slowly became reddish blue and later changed to a whitish blue. The urethral meatus constricted steadily until the fall of 1933 when two surgical incisions were made at the urethral meatus to allow free passage of urine. The patient has not had gonorrhea, previous balanitis or instruments introduced into the urethra and he has not been circumcised. The eruption as described now involves the anterior two thirds of the glans.

CASE 4—*Balanitis xerotica obliterans*. M. O. aged 22, a private patient of Dr. Henry E. Michelson stated that the anterior portion of the glans penis began to turn white and shrink about three years ago. The process has progressed until the anterior two thirds of the glans and the urethral orifice are involved. The patient received a painful preputial tear about three months before the process started. He has not been circumcised and he has not had gonorrhea or syphilis. There are no subjective sensations except a feeling of tension when he has an erection. There is no change in the urinary stream.

CASE 5—*Balanitis xerotica obliterans*. F. R. aged 24 a private patient of Dr. Henry E. Michelson developed a similar eruption about five years ago. He first noticed a decrease in the size of the urinary stream in October 1930. The eruption progressed until the entire glans and prepuce were involved. He had great difficulty in urinating by January 1931 when it was impossible to pass even a fine filiform bougie. Following the attempt to pass the bougie, about half an inch of the distal portion of the entire lining of the urethra sloughed out. The

Fig. 6 (case 3)—Section under low power showing atrophy of the epidermis and homogenization of the upper portion of the cutis in *balanitis xerotica obliterans*.

patient has to have the urethra dilated at regular intervals. After each dilation a gradual shrinking occurs, the urinary stream becomes smaller, urination becomes more difficult, and the urethral meatus gets progressively smaller. The glans remains in about the same stage of atrophy. He was not circumcised but he had had gonorrhea. Several metal sounds were passed before the eruption appeared.

Stühmer's cases began following circumcision for phimosis with or without balanitis but none of our patients had been circumcised. The glans first becomes thickened, sensitive, swollen and scaly. The swelling decreases and the affected parts become pale and parchment-like and waxy. Finally adhesions form between the glans and the prepuce. Weeping, burning and the feeling of tension persist. There may be a slight urethral discharge. The foreskin often covers and is adherent to the sulcus coronarius. The rest of the glans is covered by a whitish yellow or bluish white membrane, which shines like parchment and shows firm adherent scales in the central portion. The fully devel-

³⁴ Gougerot, Degos and Bouille. Sclerodermie de l'anneau préputial. Ann. d. mal. ven. 28: 839 (Nov.) 1934.

³⁵ Stühmer, A. Balanitis xerotica obliterans (post operationem) und ihre Beziehungen zur Kraurosis glandis et praeputii penis. Arch. f. Dermat. u. Syph. 156: 613-623, 1928.

oped eruption shows the glans to be atrophic and of a bluish to white color. Two of our cases did not go through the early weeping stage but began as atrophic white patches. Running beside the bluish, smooth sections are higher and stronger white lines of scarring, which may show some scale. The eruption is more marked at the urethral orifice. The orifice may look like a mere fissure and in severe cases urine can be evacuated only under pressure or following surgical intervention, as in case 3. The process can continue up the urethra for some distance. The urethra is hard to enter and at times even as in case 5, a fine filiform bougie cannot be passed. The disease may lead to complete urethral occlusion. In Stuhmer's cases the atrophic part was strikingly tender and could be pushed together like fine folds of tissue paper. Our cases also showed a fine wrinkling and puckering of the involved portion of the glans. Where the eruption was deeper, it did not form massive plates as in leukoplakia and kraurosis penis. Here the eruption resembled finely marked ridges similar to lichen planus of the mucous membranes. Stuhmer's cases led to obliterating atrophy of the glans and prepuce. Two of our cases are becoming progressively worse, but one seems to be improving since a mild protective ointment has been used.

Balanitis xerotica obliterans has to be differentiated from kraurosis penis. The symptoms of severe violent itching, which always accompanies kraurosis penis is absent in balanitis xerotica obliterans. Kraurosis is a disease of past middle life and most cases are seen in men over 50 years of age while balanitis xerotica obliterans is a disease of the young and most of the reported cases are in men under 30. However Müller³⁶ reported a case in a man aged 66. Gierthmühlen³⁷ described a case following circumcision in a child 18 months old. Stuhmer stressed the point that balanitis xerotica obliterans often followed circumcision for phimosis or some type of balanitis. Kraus stated that phimosis did not necessarily precede kraurosis and that balanitis when preceding kraurosis was only of casual significance. Leukoplakic balanitis can be differentiated by the coarse thickening and swelling of the glans resembling oral leukoplakia and the histopathologic picture in which epithelial proliferation in the form of acanthosis and hyperkeratosis is severe and atrophy is not present. There is no constriction of the urethra in either kraurosis penis or leukoplakia.

The microscopic anatomy of balanitis xerotica obliterans has been studied by various authors. The following description was made from a study of the section taken from patient 3. The biopsy was made in the rather advanced atrophic stage of the disease, and the excision was made from the dorsum of the glans. With the hematoxylin and eosin stain there was noted a thin, corneal lamellar scaling. Remnants of the granular layer were still present, but it was of one cell depth. There was a masked atrophy of the entire epidermis, so that the basal layer made a straight line. The individual basal cells showed decidedly rounded nuclei and intracellular edema. The continuity of the basal layer was decidedly disrupted. Immediately beneath the basal layer there was a thick zone about three times the diameter of the epidermis, consisting of homogenized connective tissue. In this zone there were no nuclei or infiltrating cells. Immediately below and at the edges of this zone there was noted a scattered

infiltrate of round cells. With the van Gieson stain the collagenous material in the homogenized zone stained a pale pink, while below it the fibers took on a deeper red but were not stained as deeply as in the normal tissue. The elastic tissue stain showed a complete absence of elastic fibers in the upper two thirds of the cutis and a normal presence in the lower third. To summarize, one would state that the essential changes were an atrophy of the epidermis and a homogenization of the upper portion of the cutis with no evidence of active inflammation. The microscopic picture closely resembled that of morphea, and it was our conception that the processes were closely related.

1228 Lowry Medical Arts Building

ABSTRACT OF DISCUSSION

DR P. H. POIRIFF, Montreal. Has Dr. Madden ever seen a patient with lichen sclerosus et atrophicus (Hallopeau) located on the penis? Many dermatologists—American, French and German, namely Oliver, Montgomery, Bizzozero, Milan, Dubreuilh and Petges—have described such cases. Schamberg and also Ormsby have asserted that lichen planus with atrophy is distinct from lichen sclerosus et atrophicus. Nomland of Chicago (*Arch. Dermat. & Syph.* 21:575 [April] 1931) said that lichen sclerosus et atrophicus should be assigned a position midway between lichen planus and circumscribed scleroderma, and he gave all their histologic and clinical characters. Does Dr. Madden think that Paget's disease may be seen elsewhere than on the nipples? Darier and Civate of Paris admitted that this may be true in exceptional cases, while Masson of Strasbourg said it could not. On the other side Busman of Pittsburgh and Woodburne of Grand Rapids (*Arch. Dermat. & Syph.* 24:396 [Sept.] 1931) described a case of Paget's disease of the glans penis.

DR JOSEPH V. KIVUDER, Philadelphia. There are many interesting points that Dr. Madden did not have time to discuss. To students of syphilis employing the dark-field microscope in the diagnosis of chancre the question of spirochetes in the flora of the male and female genitalia is of importance. One should have some idea of the spirochetes visible in the dark field microscope. *Spirochaeta refringens* is regarded by many students of spirochetalogy to be the same as *Spirochaeta balanitis*. Occasionally, one sees Vincent's spirochete and the fusiform bacillus *Treponema calligyrum* is also called *Treponema genitalis*. It resembles *Treponema pallidum* to such a degree that a differential diagnosis cannot be made microscopically. That is important in the use of the dark-field microscope in the diagnosis of concealed genital lesions. If serum from a suspected chancre on the genitalia or in the mouth cannot be obtained uncontaminated, the diagnosis cannot be made with certainty by means of the dark-field examination. *Treponema minutum* also found in smegma, is much smaller than *Treponema pallidum*. The role of spirochetes in the causation of gangrenous balanitis is a matter of controversy and that applies to other ulcerative pseudomembranous processes which have a foul odor. Vincent's spirochete and the fusiform bacillus are constantly present in such lesions and are apparently secondary invaders. The practical point is that if in secretions from beneath an adherent foreskin a number of Vincent's spirochetes and fusiform bacilli are present, it is well to perform a dorsal slit to prevent the development of gangrenous balanitis. Drug eruptions due to antipyrine and phenolphthalein may cause balanitis. Antipyrine is not frequently used now. It produces a lesion like that of phenolphthalein from which I do not believe it is possible to make a differential diagnosis. In recurring balanitis if there are lesions on the shaft of the penis and elsewhere on the skin one should consider the possibility of an eruption due to phenolphthalein or antipyrine. Such an eruption may be confined to the foreskin. I should say that in approximately 2 per cent of cases the primary lesion of syphilis is presented as balanitis. It is seen as a large number of erosive lesions that when they become confluent, very closely simulate balanitis. However, the absence of a great deal of inflammation and the free secretion of serum are points indi-

³⁶ Müller, A. Ein Fall von Balanitis xerotica obliterans. *Dermat. Wchnschr.* 92:1372-1373 (Aug. 29) 1931.
³⁷ Gierthmühlen, F. Erworbene Striktur des Meatus urethrae exter-nus beim Kleinkinde. *Arch. f. Kinderh.* 77:303-305 (March) 1926.

cating that the lesion is a chancre. As to balanitis xerotica obliterans, an atrophic process in which the urethra becomes obliterated and the foreskin becomes adherent to the glans, it is a question in my mind whether this disease is a distinct entity. One should consider the possibility of pemphigus of the conjunctiva, so-called essential shriveling of the conjunctiva. Patients with that disease present lesions similar to those of balanitis xerotica obliterans.

DR. SAMUEL AYRES JR. Los Angeles. I have had the occasion recently to observe several instances in middle aged men of a superficial erythematous plaque on the glans penis accompanied by itching of the foreskin. These cases are in no way associated with an adherent foreskin and I believe that the condition is somewhat analogous to the diaper dermatitis of an infant. As to the matter of retained urine, I think that in some of these middle aged patients there is possibly a little dribbling after urination even though they consider themselves as being reasonably careful. However, a drop of urine is retained which undergoes bacterial decomposition. Finally this rather annoying lesion is produced and may be extremely persistent yet it is surprising how simple the treatment is. In addition to extreme care in the matter of cleanliness, a little ointment of ammoniated mercury applied for two or three days seems to be sufficient to eradicate the lesion completely.

DR. JOHN F. MADDEM, St. Paul. Balanitis xerotica obliterans resembles all the aforementioned diseases in some respects, but when the clinical appearance, the course of the disease and the histopathologic picture are considered it must be admitted that it is a separate disease entity. It resembles morphea more closely than any other disease but even here there are many dissimilar points.

LOWER LOBE TUBERCULOSIS

A REVIEW

CHARLES E. HAMILTON, M.D.

AND

HARRY FREDD, M.D.

BROOKLYN

Generalizations in medicine are dangerous, particularly with regard to lower lobe tuberculosis because of its comparative infrequency.

Experience has taught us that chronic lesions in the upper lobe should be considered tuberculous until proved otherwise. Lesions in the lower lobe on the contrary should be considered nontuberculous until proved otherwise (Fishberg¹).

It is our opinion that one should not be too ready to dismiss a diagnosis of pulmonary tuberculosis because of the location of the lesion in the lower lobe.

It is easy to understand why the internist and the phthisiologist make diligent search for confirmatory evidence of tuberculosis in upper lobe lesions, while on the other hand, they favor a diagnosis such as unresolved pneumonia, chronic pneumonitis, bronchiectasis abscess, syphilis and tumor when the lower lobe is affected. Tuberculosis becomes a remote possibility and is invariably easily dismissed by roentgen examination and one or more negative sputums.

Data on lower lobe tuberculosis is contradictory. Laënnec² whose classic works on the development of tubercle have come down practically unchanged through the past century, stated that it is extremely rare for excavations to develop first in the middle or base of the lungs. Fowler³ also states that the apex is the first site of parenchymal activity.

So generally has this opinion been accepted that even today primary basal involvement is regarded as extremely rare.

Garon, Lyall and Monta⁴ claim that râles of long standing below the middle of the chest are almost as diagnostic of a nontuberculous lesion as râles in the upper half of the chest are suggestive of tuberculosis. However, they believe that 10 per cent of all tuberculosis is primary in the lower lobes.

Fagge⁵ stated that "tuberculosis never spreads upward from the base through the upper lobe. What has sometimes been called chronic basal phthisis is a distinct affection which has been described under the name of chronic pneumonia."

In modern times one finds Fishberg¹ stating that basal tuberculosis is extremely rare. Landis⁶ states "My opinion concerning basal tuberculosis is still unchanged, children may have it at the base, but adults practically never."

Pottenger⁷ does not discuss it at all. Rabbiosi⁸ stated that there are frequent types of tuberculosis of extra-apical origin, but he was referring to lateral and infraclavicular lesions rather than to localizations in the lower lobes. Fraenkel⁹ stated that the early infiltrate in tuberculosis may be anywhere in the lung, being most rarely in the apex. He found localizations in the lower lobes. It was his experience that these may persist for weeks, months and years and that during that time the patient may apparently be in the best of health and yet, when softening and regional spread occur, symptoms appear. Similarly, Pindell¹⁰ in 1932 called attention to lower lobe tuberculosis and warned that this condition is treacherous. He also expressed the belief that this may exist for years without noticeable symptoms but that the great majority eventuate into manifest disease.

INCIDENCE

Kidd¹¹ found two instances in 412 cases of pulmonary tuberculosis. He stated that the incidence varied from one to eighty cases to one in 500 according to different writers. Rosenblatt¹² found three cases in 1000, DuFault¹³ found one in 365, Dunham and Norton¹⁴ found twenty-six cases in two years in a 250-bed hospital. Ross¹⁵ found eleven cases in sixty tuberculous nurses and Lathrop and Lyman¹⁶ found eighty-eight cases among 2,809 patients with tuberculosis.

In the wards for tuberculous adults at Kings County Hospital from September 1934 to January 1935, we have had ten proved cases of sole involvement of a lower lobe due to tubercle bacilli. Of 198 newly admitted males, three had lower lobe tuberculosis, and of 151 newly admitted females, seven had proved cases of strictly lower lobe lesions due to tubercle bacilli, showing an incidence of over 3 per cent.

We hasten to add that this obviously cannot be considered a true picture of the incidence of lower lobe

tuberculosis for the reason that our series is small and because many patients with lower lobe tuberculosis have remained with an incorrect or without any diagnosis in the medical wards

MODE OF DEVELOPMENT

Colton¹⁷ states that it would seem that the most plausible explanation of basal lesions would be rupture of a tracheobronchial or hilar lymph node into a large bronchus, and lodgment of a massive infection in the terminal bronchioles and alveoli producing a bronchopneumonic involvement. H. K. Pancoast, in discussing Norton and Dunham's paper, expressed the belief that lower lobe tuberculosis is an atypical manifestation of miliary tuberculosis and is due to blood stream infection.

SYMPTOMS

In the series of cases reported by Lathrop and Lyman, cough was present in 98 per cent, expectoration in 86 per cent, loss of strength in 81 per cent, loss of weight in 76 per cent, fever in 64 per cent, pleural pain in 59 per cent, dyspnea in 50 per cent, hemoptysis in 29 per cent and casual positive sputum in 28 per cent.

Fig 1 (case 3)—Tuberculosis of the lower lobe of the left lung

Fig 2 (case 5)—Tuberculous involvement of the lower lobes

Fig 3 (case 6)—Before pneumothorax was induced

In our ten cases we found cough present in all, hemoptysis in eight, night sweats in six, loss of weight in five, fever in five and pain in the chest and expectoration in two.

We believe that the symptoms of lower lobe tuberculosis are the same as those in upper lobe tuberculosis. It is apparent that these patients were referred to the tuberculosis ward because of hemoptysis and other outstanding symptoms of phthisis.

DIAGNOSIS

That a diagnosis of lower lobe phthisis may be difficult or even impossible to make for a long time can readily be seen if it is remembered that the sputum is often negative.

Excavations in lower lobe cases are less "open" than in upper lobe cases, and an obstruction in the bronchi may interfere with the free evacuation of the cavity contents (Gordon and Charr¹⁸). Indeed in order to obtain a positive reading, there must be 100,000 tubercle bacilli per cubic centimeter present, if examined by ordinary methods (Pottenger¹⁹ and Corper²⁰).

²⁰ Corper H. J. The Certified Diagnosis of Tuberculosis. J. A. M. A. 91: 371 (Aug. 11) 1928.

Pinner²¹ found that, in a series of 238 negative sputum examinations, fifty-six were found positive by other methods of examination (concentration, animal inoculation, culture). Burgess Gordon suggested the use of 5 drops of saturated solution of potassium iodide every four hours for from six to eight doses to help obtain a positive sputum in difficult cases.

If, in addition, it is remembered that the roentgenologist's interpretation often suggests unresolved pneumonia, abscess, tumor, syphilis, bronchiectasis or chronic pneumonitis rather than tuberculosis solely because the lesion is located in the lower lobe, it can readily be seen how easy it is to rule out tuberculosis if one is so inclined. As a result, chronic lower lobe processes are perhaps too often attributed to other causes, i. e., cocci.²² Yet Lathrop and Lyman found that 67 per cent of lower lobe lesions were due to tuberculosis and only 33 per cent due to other causes.

If in early cases the casual sputum examination or even concentrates and the roentgen interpretation may be misleading, what can be depended on? The answer is the history and clinical course.

We have found in the few cases that we have had the opportunity to observe that the history and clinical course are our most valuable aids until confirmatory evidence is available.

The clinical course of lower lobe tuberculosis does not differ from that of upper lobe tuberculosis. Furthermore, as Fraenkel and Pindell have pointed out, it may be necessary to observe these patients for weeks, months or even years before softening and regional spread occur to make a definite diagnosis possible.

PROGNOSIS

Dunham and Norton on the basis of their series of twenty-six cases have decided that basal lesions are virulent. They are of the opinion that basal lesions occur only in those patients who have tuberculosis elsewhere in the body. In other words, they consider that lower lobe tuberculosis is always part of a generalized tuberculosis. In the few cases we have had we have found no involvement anywhere else in the body. Dunham and Norton obtained poor results in these cases probably because their patients were colored and

²¹ Pinner M. J. Lab. & Clin. Med. 17: 611 (April) 1932.
²² Riesman Am. J. M. Sc. 146: 313, 1913. White W. C. Tr. Nat. A. Study & Prev. Tuberc. 11: 140, 1915. Finkler Dittmar. Infektionen der Lungen durch Streptococci und Influenzabacillen. Bonn F. Cohen 1895. Garvin A. H. Am. Rev. Tuberc. 1: 1, 1917.

in them tuberculosis is always virulent. Colton, in his article also stated that he considers these cases to be grave.

We are unable to agree with these statements. Of our ten patients only one has died, and she was colored. The others were treated by collapse and phrenicectomy and are doing well.

REPORT OF CASES

CASE 1—P O, a white woman, aged 28, admitted Oct 8 1934, complained of cough of fifteen months' duration, night sweats, loss of weight, hemoptysis and fever. Her past and family history were negative.

Examination revealed dullness in the right interscapular region, rales and increased breath sounds. There was no clubbing of the fingers. Repeated sputum examinations showed positive results. The sputum was not copious or fetid. X-ray films revealed clear upper lobes and a cavity in the upper part of the lower field of the right lung.

Repeated attempts at pneumothorax were unsuccessful. Right phrenicectomy was performed on October 26 and was successful. The patient has gained 9 pounds (4 Kg) in weight, the right diaphragm is raised, the cavity is smaller, the temperature is now flat, but the sputum is still positive.

Fig 4 (case 6) —After pneumothorax was induced.

Fig 5 (case 7) —Tuberculosis of the lower lobe of the left lung

Fig 6 (case 8) —Bronchopneumonic infiltration of the lower lobe of the left lung

CASE 2—A P, a white woman aged 32, was transferred to Kings County Hospital on Aug 4, 1934, from the Israel-Zion Hospital, complaining of pain in the right chest, cough, hemoptysis and low grade fever since July 31.

Her past history revealed that following a cholecystectomy in 1933 pleurisy developed on the right side and the patient was in bed for three months. Her family history was negative.

Examination revealed impaired resonance over the apex of the lower lobe of the right lung, bronchovesicular breathing and numerous rales. The sputum was positive and the temperature was over 100 F. Roentgen examination revealed bronchopneumonic infiltration in the lower lobe of the right lung and evidence of destruction and cavitation in the middle lobe.

Pneumothorax was induced and a good collapse was obtained. The patient appears to be improving, the temperature is now flat and the sputum is negative.

CASE 3—C N, a white woman aged 20, admitted May 17 1934, complained of cough, fever and pain in the left side of the chest of one week's duration.

Her past history revealed that her case had been diagnosed as tuberculosis in 1932 and she had been at the Municipal Sanatorium at Otisville for six months. She was discharged as an arrested case and the board of health had found the sputum negative. Her father died of tuberculosis.

Examination revealed dullness and fine rales over the lower lobe of the left lung posteriorly. The case was characterized by low grade fever, weakness, cough and expectoration. The concentration method for sputum examination was carried out and numerous tubercle bacilli were found. X-ray plates revealed

a lesion of almost homogeneous density in the lower lobe of the left lung. The upper lobes were clear.

Pneumothorax was induced. The patient gained 12 pounds (54 Kg) and improved so much that she was discharged August 25 to continue her treatments at the board of health.

CASE 4—C S, a Negress aged 19, admitted May 22, 1934, complained of cough, fever, night sweats and hemoptysis of one month's duration.

Her past history revealed that she had 'caught cold' in November 1933 and had never fully recovered. The case had a septic course with profuse expectoration and hemoptysis.

The chest showed impaired resonance, bronchial breathing and many fine rales over the lower lobe of the right lung posteriorly. The sputum on six occasions was negative but then became consistently positive. X-ray films revealed an irregular involvement of the base of the right lung and a distorted enlarged hilar shadow. The upper lobes were clear. The Wassermann reaction was 4 plus.

The patient's condition became progressively worse. The process extended into the upper lobe of the right lung. She finally consented to pneumothorax, which was started September 10. Her condition was unimproved and on September 18 the process was found to have spread over to the upper lobe of the left lung. The patient died October 18.

CASE 5—A C, a white man, aged 21, admitted Dec. 11, 1934, complained of cough, hemoptysis, loss of weight, low grade fever and night sweats of four months' duration. His past history was unimportant.

Examination revealed involvement of the lower lobes of both lungs with signs of vomicae. Roentgen examination showed diffuse interstitial changes in the lower lobes of both lungs with cavitation. The upper lobes were clear. The sputum was found to be loaded with tubercle bacilli when studied by the concentration method.

The patient was given conservative treatment as he refused pneumothorax, and his condition has improved. However the sputum still contains tubercle bacilli.

CASE 6—M L, a white man aged 21, admitted Oct 22, 1934, complained of cough of nine months' duration, fever at night, night sweats and hemoptysis. His past history revealed only that at 10 years of age he was sent to the country because of malnutrition. His mother has an 'arrested case' of tuberculosis.

Examination revealed dullness over the middle lobe of the right lung anteriorly and the upper part of the lower lobe posteriorly, with numerous rales. The sputum was positive. X-ray films revealed clear upper lobes with a large cavity in the midfield of the right lung. Pneumothorax was started on November 5 and a good collapse was obtained. The patient was transferred to Bedford Hills, improved.

CASE 7—L S, a white woman, aged 29, admitted Aug 17 1934, complained of cough, expectoration, night sweats and loss of weight. Her illness dated back to May 1934 when pleurisy developed on the left side and persisted.

Roentgen and sputum examinations by the board of health were negative, but after many sputum examinations were made positive reports were obtained. The sputum after admission to the hospital was consistently positive. X-ray films revealed an area of consolidation in the lower lobe of the left lung. On September 17 pneumothorax was started. A good collapse was obtained and the sputum became negative. The subsequent course was uneventful save for the development of a pleural effusion, which cleared up. She was finally discharged to continue her treatment at the board of health.

Fig 7 (case 10)—Exudative lesions in the lower lobes

Her family history revealed that her father had hemoptysis but studies made by the board of health were negative for tuberculosis.

Examination revealed dullness, and fine rales in the lower lobe of the left lung with bronchovesicular breathing. Roentgenograms showed bronchopneumonic infiltration in the lower lobe of the left lung. The sputum was positive (six times). She is being treated by bed rest and the affected area has undergone slight resolution.

We feel that pneumothorax will be resorted to in this case, although the patient has gained weight (8 pounds or 3.6 Kg) and the sputum is now negative.

CASE 9—M. S., a white man aged 26, admitted Nov. 3, 1934, complained of cough, hemoptysis, night sweats and loss of weight of four months' duration.

His past and family history were negative. His present illness started four months before, when he "caught cold." He had an evening fever and occasionally blood-streaked sputum. Examination revealed dullness, bronchovesicular breathing and numerous rales in the left subscapular region. X-ray films revealed a caseous pneumonic process affecting the lower lobe of the left lung with evidence of a cavity in the upper part of the lobe. The upper lobes were clear. The sputum was positive. The patient stated that thirty sputum examinations made before admission were negative.

Pneumothorax was started on November 17. The patient improved and gained weight, and the sputum became consistently negative. However, there seemed to be a spread to the lower and middle lobes of the right lung in January although there were no confirmatory physical signs. He was finally transferred to Seaview for continued treatment.

CASE 10—E. M., a white woman, aged 21, was admitted Dec. 11, 1934. Her chief complaint was hemoptysis of one day's duration. Her past history revealed that she had an appendectomy performed, and a diagnosis of tuberculous peritonitis was made. At that time pleurisy developed on the right side and the sputum became positive. She has been at Seaview for the past eight months and has been treated conservatively. However, the cough has persisted.

Examination revealed dullness with diminished breath sounds and numerous rales over the lower lobes of both lungs posteriorly. X-ray films revealed an exudative lesion in the lower fields of both lungs. The upper lobes were clear. The sputum has been negative on four occasions and positive twice. The temperature has been slightly elevated. Pneumothorax therapy will probably be instituted.

CASE 8—L. McG., a girl, aged 15, admitted on Sept. 3, 1934, complained of hemoptysis, cough, expectoration and loss of weight (6 pounds, or 2.7 Kg) for the past month. She had been admitted the year before with similar complaints, but studies for tuberculosis had been entirely negative. Roentgen examination by the board of health two weeks before admission was negative. Fifteen sputum examinations were negative.

SUMMARY

1 In ten cases of lower lobe tuberculosis, there was no involvement of the upper lobes.

2 The history and the clinical course are the most valued aids in making a tentative diagnosis.

3 Negative sputum examinations do not rule out lower lobe tuberculosis.

Clinical Notes, Suggestions and New Instruments

TABLE KNIFE IN CRANIUM CRANIECTOMY WITH COMPLETE RECOVERY

JOSEPH E. FULD, M.D., NEW YORK

While many skull injuries have been reported, this case is of such an unusual character that I felt it would be of interest to record it.

REPORT OF CASE

History—In 1930 the patient was shot by a patrolman, and four bullets were removed at Fordham Hospital—two from the neck and two from the right arm. From this, he recovered completely.

Oct. 24, 1934, the patient, while an inmate at the penitentiary, was attacked and forcibly held by two prisoners while a third prisoner viciously struck him a terrific blow in the head with a table knife, which had been previously sharpened to a point. Had it not been for the fact that the patient suddenly ducked his head forward and downward to protect himself the blade would probably have entered the skull in a horizontal plane. What did occur was a deviation of the line of penetration obliquely downward and backward, so that the vital structures were spared.

Fig 1—Lateral view taken before operation

The patient was seen immediately by the resident physician who stated that the knife was buried to the hilt about one-half inch above the root of the nose. There was no evidence of any hemorrhage from the site where the blade had entered. The patient was expectorating a considerable amount of blood.

An attempt was made by the resident physician to remove the blade but the handle snapped off leaving about one-half inch of the blade above the surface of the wound. A remark

able fact is that the patient at no time showed any evidence of pain or distress and was perfectly calm and collected, notwithstanding that 4 inches of blade was embedded in the skull and cranial cavity.

The patient was removed at once to the Correction Hospital, where I operated on him under a general anesthetic about two hours after the assault.

Examination—The patient, a white man, aged about 23, was lying quietly in bed, showing no signs of pain or distress. Examination showed that there was protruding from the forehead about one half inch of the proximal end of the blade of a table knife. Lumbar puncture was done and 15 cc. of spinal fluid was removed. There was a considerable amount of blood in the spinal fluid. Dr. Bonoccolto, attending ophthalmologist, who examined the patient, reported that the pupillary reflexes were normal, the ocular reflexes were normal, the media were clear, the fundus was normal, and there was no evidence of any impairment of vision. There was a considerable amount of bloody expectoration. Neurologic examination by Dr. R. A. Gerber was entirely negative.

A sketch (fig. 2) made from the roentgenogram (fig. 1) by Dr. L. Vosburgh Lyons represents a sagittal section of the

Fig. 2—Sketch from the roentgenogram (fig. 1), representing a sagittal section of the skull. By referring to this sketch the structures through which the blade passed can best be indicated. After penetrating the frontal bone the blade entered the cranial cavity. The edge of the blade is embedded in the cribriform plate of the ethmoid bone.

skull. By referring to this sketch the structures through which the blade passed can best be indicated. After penetrating the frontal bone, the blade entered the cranial cavity. As it is in the midline the blade probably passed between the under surface of the frontal lobes of the brain and so escaped penetrating them. However, it is observed that at this point the edge of the blade is embedded in the cribriform plate of the ethmoid bone, so that the dura and its vessels must have been injured. The extravasation of blood at this point is probably the source of blood that was found in the spinal fluid. The olfactory nerve fibers pass into the brain here and many of them must have been injured.

It is evident that as a result of this injury there was a real danger of meningitis starting at this point, owing to contamination from the knife or from bacteria from the nasal cavity, which could either travel up through the ethmoid bone or be introduced into the meninges as the knife was removed.

The tip of the instrument was embedded in the sphenoid bone. The cavernous sinus, the pituitary gland and the optic chiasm were avoided above by a fraction of an inch. Infection at this point could be drained through the nasal cavity. Had the blade passed a small distance to the right or left it would have severed the internal carotid artery with serious results.

Roentgenograms taken before the operation revealed a metallic foreign body, about 4 inches in length, which entered the skull through the orbital ridge of the frontal bone slightly to the left of the median line. In its penetration the object went through the frontal sinus, extending for a short distance along the base of the skull, through the anterior cerebral fossa. The farthest point of the foreign body is noted in line with the acoustic meatus, having probably penetrated through the

Fig. 3—Showing the blade and handle of the table knife used in the assault. The full length of the blade, which had been ground and sharpened to a point in the form of a stiletto was embedded in the skull and was removed by open operation.

sphenoid sinus. The anterior end of the foreign body is seen protruding from the skin.

Operation—A 4 inch blade entered the patient's skull about one-half inch above the root of the nose about one-eighth inch to the left of the midline and in an oblique direction at an angle of about 45 degrees with the horizontal plane. From the x-ray film and at operation, it was found to pass obliquely downward and backward through the frontal sinus, penetrating the sphenoid bone and its cells, the point being apparently embedded in the body of the sphenoid bone and protruding through the roof of the pharynx.

Before resorting to an open operation, I made an attempt to remove the blade by means of heavy forceps, but the attempt was unsuccessful. It became necessary to resort to a general anesthetic, and the following procedure was adopted.

About 1 inch from the embedded knife blade, the wound of entrance was enlarged and extended about 1½ inches vertically. An opening was bored into the skull by means of a Hudson drill. Then the intervening bridge of bone was cut away by means of rongeur forceps. When this was completed, the Hudson bone rongeur forceps was employed to remove enough of the bone surrounding the blade, so that sufficient play was allowed to loosen it at its distal end by tapping the knife laterally. When it was evident that the blade was slightly loose, the blade was removed by means of forceps.

Hemorrhage at the point of entrance was controlled by iodoform packing. A postnasal packing was used to control the hemorrhage due to the wound in the posterior pharyngeal wall.

Progress Notes—The next day the patient was seen by Drs. Broones and Tateka, attending otolaryngologists. Examination of both nostrils revealed no evidence of injury or hemorrhage.

Fig. 4—Appearance of the scar on the forehead of the patient four weeks after operation.

Packing was removed from the nasal pharynx, and posterior rhinoscopy revealed a transverse slit one-fourth inch long in the posterior nasopharynx to the right of the midline and approximately one-half inch below the lower border of the sphenoid ostium

Six days after the operation the packing was removed from the wound, and a profuse serous discharge was noted. Eleven days after the operation, both the upper and the lower angles of the wound had completely healed. A narrow slit in the center of the wound was still open, discharging a serous fluid three days later the patient was up and around the ward.

During the entire postoperative period, the patient had no elevated temperature and no complaints. Repeated examination revealed no evidence of any cerebral injury.

There was an uneventful recovery after a period of eighteen days in the hospital. The present condition is excellent, about one month after injury.

COMMENT

Numerous cases of serious penetrating wounds of the skull have been reported. I am offering the facts of this case, especially for the following reasons:

- 1 The type of weapon used (an ordinary table knife)
- 2 The terrific force that must have been employed to drive it to the hilt, embedding it 4 inches within the skull
- 3 The postoperative course, which was uneventful
- 4 Above all, the fact that the patient reacted with no shock or distress, either before or after the removal of the blade.

It is surprising to note that meningitis did not develop here, while in most cases it usually is expected.

125 East Eighth-Fourth Street

Special Article

GLANDULAR PHYSIOLOGY AND THERAPY

ANTIANEMIC MATERIAL OF LIVER AND STOMACH

RANDOLPH WEST, MD
NEW YORK

NOTE.—This article and the articles in the previous issues of THE JOURNAL are part of a series published under the auspices of the Council on Pharmacy and Chemistry. Other articles will appear in succeeding issues. When completed, the series will be published in book form.—Ed

The observation of Minot and Murphy¹ that adequate liver feeding induces and maintains remissions in pernicious anemia has led to far-reaching results. In addition to establishing the first effective therapy in this and some allied diseases, it has initiated investigations that have resulted in a marked revision of ideas concerning gastric physiology and deficiency diseases and should further contribute materially to our knowledge of cellular physiology, particularly that of nerve tissue and bone marrow.

Though the idea of dietary therapy in the treatment of pernicious anemia is not new,¹ the earlier, moderately encouraging reports that appeared were not sufficiently convincing to rule out the possibility of spontaneous remission, and the life span of the patients treated was not significantly increased. Mosenthal² had shown that the forced feeding of a diet rich in meats restored

nitrogen balance in pernicious anemia. Gibson and Howard³ had found that a diet rich in iron, and incidentally containing considerable amounts of liver, established a positive nitrogen and iron balance and appeared to increase the frequency of remissions. The work of Whipple and Robschert-Robbins⁴ on the anemia of dogs secondary to hemorrhage demonstrated the efficacy of the addition of liver to a basic diet in accelerating hemoglobin regeneration, and the high nutritive value of liver and kidney protein had been long established.⁵ There were also certain observations¹ suggesting that a high fat intake was undesirable. These considerations, together with the analogy to several deficiency diseases such as sprue, pellagra and beriberi, and the nature of the changes in the bone marrow, led Minot and Murphy to devise a diet containing from 120 to 240 Gm of liver, 120 Gm of beef, 300 Gm of vegetables and 40 Gm of fat daily. Bread and cereals were added for caloric value. The clinical improvement in the first forty-five patients to whom the diet was administered was dramatic, and further observations showed that liver or kidney was the essential ingredient, a daily intake of 240 Gm proved effective in causing a return to and maintenance of a normal red cell and hemoglobin level.

EFFECTS OF LIVER FEEDING IN PERNICIOUS ANEMIA

The administration of approximately half a pound of cooked liver or kidney daily to individuals ill with pernicious anemia is followed by a marked rise in the blood count, a definite but much slower improvement in spinal cord symptoms, and a disappearance of sore tongue and diarrhea, but no return of gastric acidity. The patient, barring severe cord symptoms, is rapidly transformed from a state of invalidism to practically unimpaired health and strength, a sense of well being often appears within a day after the administration of large doses of liver or liver extract.

The changes in the blood and marrow are most striking. By the fourth day after starting liver feeding the reticulocytes,⁶ usually less than 2 per cent before treatment, increase sharply and reach a peak between the seventh and the tenth day, the height of which is inversely proportional to the initial red cell count. From red cell levels of one million, reticulocyte peaks of 40 per cent or more may follow, with two million red cells the peak may be 20 per cent and with three million 8 per cent, while initial red counts of over three and a half million are not followed by any significant rise in the reticulocytes. Within three weeks after the initiation of therapy the reticulocyte count again sinks to normal levels. The red blood count and hemoglobin usually begin increasing shortly after the reticulocyte peak and continue to rise until approximately normal values are attained within from one to two months. The color index also tends to return to 1 or less, and, although poikilocytosis disappears, an examination of the blood smear generally reveals the presence of a few

macrocytes The white blood cell and the platelet counts also return to normal It is of interest that during the first week of therapy there may be a transitory appearance of a few myelocytes Occasionally patients on the liver diet develop a marked eosinophilia, which has not been noted when stomach preparations or partially purified injectable liver extracts are used⁷

Peabody⁸ studied the bone marrow by trephining the tibia at various stages of the disease When the blood count is low there is a marked hyperplasia, the fatty marrow of the long bones being largely replaced by red marrow, which is characterized microscopically by the accumulation of large numbers of megaloblasts As the peripheral blood picture improves, the hyperplastic marrow reverts to the normal type with a disappearance of megaloblasts It appears that the active liver material causes the megaloblasts to mature and reach the peripheral circulation first as reticulocytes, later as normal adult blood cells During the reticulocyte rise there is a sharp increase in the urinary excretion of uric acid,⁹ probably derived from disintegrating red cell nuclei

The increased excretion of urobilin in the stools and urine, the elevation of bile pigment in the serum, and the general organ siderosis, long interpreted as evidences of the presence of an active hemolytic toxin, also return to normal following adequate liver therapy¹⁰ The lowered serum protein and cholesterol values, too, resume their usual levels¹¹ In short, all the abnormalities that have been observed in the morphology and chemistry of the blood disappear, with the exception of a slight tendency to macrocytosis

The changes in the nervous system have to be judged by the clinical course The essential lesion is a myelin sheath degeneration,¹² affecting chiefly the dorsal columns and pyramidal tracts of the spinal cord, and to a lesser extent the white matter of the brain and peripheral nerves Pathologic studies of the nervous system following effective therapy have not been reported, but signs and symptoms indicate that with adequate amounts of liver the progress of the lesions is arrested, and a gradual improvement takes place over a period of months or even years¹³ The most important point in treating patients with spinal cord involvement is the maintenance of the blood at or above normal levels,¹⁴ for even with the red blood count as high as four million the development of cord lesions has been observed, while with red cells at five million or better this has not taken place This probably accounts for the discrepancies in the literature reviewed by Fouts,¹⁵ who found that vitamin B was inert in the treatment of cord lesions The most severe cases, even those presenting bed sores, paralysis and bladder involvement, may respond to adequate parenteral liver therapy

The point of view which has also been advanced that, while peripheral nerve lesions may improve, spinal cord lesions do not, is hardly in keeping with the disappearance of the Babinski reflex and ataxia The rate of improvement in spinal cord symptoms is inversely proportional to their duration, the outlook for complete recovery being much brighter if symptoms have been present only for a few months, but even those of years' duration may show improvement with prolonged intensive treatment

The response of the gastro-intestinal tract to liver therapy is of great interest The sore tongue rapidly improves, and the papillary atrophy of that organ may gradually become less The diarrhea that at times is present usually disappears

The central lesion of pernicious anemia, the gastric anacidity, however, persists It has long been known that achlorhydria is practically always present in classic Addison's anemia¹⁶ and often exists for many years before the onset of involvement of the blood or nervous system It has now become clear that with rare exceptions¹⁷ it persists¹⁸ after liver therapy has brought about a return of the blood and marrow to normal and has favorably affected the nervous system Though the gastric atrophy thus appears to be the most constant feature of the disease, it must be noted that following gastrectomy in man the development of pernicious anemia is not constant,¹⁹ while the disease has not yet been produced in animals by this method It seems that, important as gastric atrophy is, there may be additional factors, possibly an inability to synthesize liver material in the body, that are necessary for the development of the disease It is also well known that the disease is very rare under the age of 30, though this may be due to the rarity of gastric atrophy in the young

PARENTERAL ADMINISTRATION OF LIVER EXTRACT

The chemical studies of Cohn and his associates and of others²⁰ of the nature of the material in liver active in pernicious anemia led to the preparation of liver extracts that were suitable for intravenous or intramuscular administration These earlier methods, however, involved such huge amounts of material that the product was not generally available Gänsslen²¹ and Castle,²² employing a simpler technic, introduced extracts of such potency that maximal reticulocyte responses were obtained following the daily injection of material derived from 15 to 20 Gm of liver To obtain a similar response by oral administration, from fifty to seventy times as much liver is necessary It became clear that the active material in liver was either poorly absorbed from or partially destroyed in the gastro-intestinal tract

Therapeutically these observations were of the greatest importance, and they opened the way to an effective

control of the disease by the injection of a suitable amount of liver extract every one to three weeks, and to the intensive treatment of certain refractory cases and of those with involvement of the central nervous system

The question of the standardization of liver extracts and adequate dosage is vexing. The only available method of standardization has been the reticulocyte response of an untreated case of pernicious anemia to a submaximal dose of liver extract, the paucity of cases has rendered standardization difficult. Bethell²³ has pointed out that the total reticulocyte production is probably more important in standardizing extracts than is the reticulocyte percentage on any given day. Recently a method of assay utilizing the reticulocyte response of normal guinea-pigs has been devised by Jacobson²⁴ and holds great promise but is not yet in general use. The statement that a given volume of extract is derived from a given weight of liver may be misleading, as losses of potency occur in manufacture. It is therefore wisest for the clinician to treat each case individually, adapting the dosage to the needs of the patient.

The initiation of a remission and attainment of normal blood values is comparatively simple, after that, proper amounts of extract should be given at sufficiently frequent intervals to maintain the red blood count at or above normal levels. This is imperative in patients with spinal cord involvement, who, when desperately ill, should be given amounts of parenteral extract daily that will normally maintain a patient for intervals of two or even three weeks. Most of the commercial extracts are prepared so that injections of from 3 to 10 cc will be followed by a maximal reticulocyte response, and a similar amount injected every one to three weeks will maintain an average case. In general, older patients, particularly those with marked arteriosclerosis, require larger doses.

Certain preparations may be injected slowly intravenously,²⁵ but occasionally severe reactions follow and the intramuscular route is to be preferred unless very large doses are imperative. A few severe reactions may follow even intramuscular injections, characterized by urticaria, falling blood pressure, vomiting and intestinal peristalsis. These are usually due to idiosyncrasies of the patient rather than to impure preparations and have been observed with highly purified material. "Allergic" individuals particularly should be treated with caution.

It must also be borne in mind that multiple deficiencies may occur and that, while iron is generally superfluous, in certain instances it may be needed to maintain normal hemoglobin values.

THE NATURE OF THE ANTIANEMIC MATERIAL IN LIVER

The absence of a nonclinical test for activity has greatly retarded investigation of the chemical nature of the material in liver active in pernicious anemia. The earlier work²⁶ soon established certain facts. Protein could be removed by heat and proved inert. All active material could be precipitated from the filtrate by

phosphotungstic acid or by Remeke's salt, and it could be regenerated from these precipitates. Unfortunately the salts of gold, silver, platinum or mercury destroy clinical activity, as does exposure to normal sodium hydroxide at room temperature, or boiling with mineral acids. Heating to 80 C or even 100 C at pH 5.0 does not lessen clinical potency. The active material is readily soluble in water, and, when partly purified, it is also soluble in large volumes of slightly acid 95 per cent alcohol. It is insoluble in ether. The reported isolation of a crystalline quinine salt was incorrect.²⁷

The best preparations obtained have given no biuret reaction, they contain carbon, hydrogen, oxygen and nitrogen. Phosphorus and sulphur are absent. Intravenous doses of 75 mg have been followed by maximal reticulocyte responses. In the absence of crystallization it is possible that the effects obtained are due to traces of impurities, but this seems improbable.

In addition to the material active in pernicious anemia, there is evidence that another chemical fraction of liver has to do with the accelerated hemoglobin formation following hemorrhage described by Whipple²⁸. This fraction is not rich in the antipernicious anemia material and probably contains a mixture of substances that may act as building blocks for hemoglobin.

GASTRIC FUNCTION IN PERNICIOUS ANEMIA

In 1928 the experiments of Castle²⁹ clarified the role of the stomach in this disease and added a new chapter to gastric physiology. The almost universal relationship of achylia gastrica to Addison's anemia and to subacute combined degeneration of the spinal cord has been mentioned, as has the fact that the achylia precedes clinical symptoms and persists after otherwise effective liver therapy.

Castle has shown that gastric digestion liberates antianemic material from certain foodstuffs which before digestion had no antianemic properties. His classic experiment consisted in feeding a patient suffering with pernicious anemia a half pound (225 Gm) of rare hamburger steak each morning, and 200 cc of fresh normal human gastric juice each evening for ten days. There was no blood response. For the next ten day period the steak and gastric juice were fed together, and a rise in reticulocytes and blood count followed, analogous to that described for liver feeding. The reaction of the gastric juice with the beef steak may also be carried out in vitro by incubation in slightly acid solution, and positive responses follow when the resulting product is administered orally to patients. In the earliest experiments a normal individual ate 250 Gm of steak and regurgitated it after a short time, the product was then administered by stomach tube.

The factor in beefsteak was called the extrinsic factor and that in gastric juice the intrinsic factor, the lack of which causes Addison's anemia.

The intrinsic factor is thermolabile, heating to 70 C completely inactivates it. It is presumably an enzyme,

but experiments carried out by substituting various preparations of pepsin and rennin for fresh gastric juice have yielded negative results

Castle has shown³⁰ that there may be a dissociation of gastric acidity and the intrinsic factor. Cases of tropical sprue with normal stomach acid values may present an anemia that responds to liver, while elderly individuals often have achlorhydria but no anemia. Acid gastric juice from an anemic patient with sprue, when mixed with meat and fed to a patient with Addison's anemia, failed to induce a reticulocyte response, while achlorhydric gastric juice from an elderly nonanemic individual contained the intrinsic factor by the same test. Isaacs and Goldhamer³¹ have called attention to the diminished quantity of gastric juice secreted in pernicious anemia; they collected 1,500 cc during a period of eight weeks from five patients. This, when incubated with meat and fed to a patient, was followed by a fair rise in reticulocytes.

The extrinsic factor has been studied by Strauss and Castle,³² who substituted various substances for the beefsteak of their original experiment and digested them with normal gastric juice. By this method the extrinsic factor has been found to be absent from casein, gluten, nucleoprotein from hen's blood, and nucleic acid of yeast and of animal origin. Washed beef muscle protein contained moderate amounts, and spleen pulp and autolyzed yeast large amounts of the extrinsic factor. The further observations that the extrinsic factor in yeast was not destroyed by autoclaving and was soluble in 80 per cent alcohol led to the suggestion that it might be identical with or closely allied to vitamin B₂ (G). Further work has made this suggestion untenable, for Lassen,³³ Wills³⁴ and Diehl and Kühnau³⁵ have failed to obtain responses on feeding various sources of vitamin B₂ and gastric juice to patients having pernicious anemia. Furthermore, potent liver material has been purified till free from this vitamin.³⁶

That Cassel's yeast preparation (Vegex) contained the extrinsic factor is clear, and the observations of Wills^{34b} on tropical macrocytic anemias, in which the intrinsic factor is presumably present and the extrinsic factor lacking in the diet, confirm this. Adequate reticulocyte responses followed the feeding of Marmite (a yeast preparation) autoclaved at pH 5.0, and an 80 per cent alcoholic or an aqueous extract of Marmite. No response was elicited with alkaline autoclaved Marmite, vitamin B₂ from egg white, or vitamins B₁ and B₆. The experiments of Miller and Rhoads³⁷ also indicate that vitamin B₂ and the extrinsic factor are not identical; certain sources of the extrinsic factor are

poor in vitamin B₂. They found both present in egg white, however, failing to confirm the observation of Wills.

ANTIANEMIC FACTORS IN DESICCATED STOMACH AND IN GASTRIC JUICE

The evidence of the essential role of the stomach in the causation of pernicious anemia was now firmly established, and in 1929 Sturgis and Isaacs³⁸ administered to patients powdered hog's stomach, defatted and desiccated at low temperature. The daily administration of from 20 to 30 Gm of the desiccated material derived from 150 to 200 Gm of the fresh organ was promptly followed by a response analogous to that already described for liver feeding, and all the effects obtainable by the oral administration of liver and liver extracts were duplicated with desiccated powdered stomach. Reports of active extracts of stomach suitable for injection have been published by Gänsslen,³⁹ the daily dose being the material derived from 4 Gm of gastric mucosa. No chemical details are given. Other workers have failed to confirm this observation.

All activity of the stomach preparation is lost on heating for an hour at 70 C, and the desiccation is usually carried out below 45 C. The material must not be heated before administration to the patient. The question at once arises as to the relationship of stomach material to liver material, and to Castle's two factors. It seems highly probable that in feeding whole desiccated stomach one is feeding Castle's extrinsic and intrinsic factors simultaneously. Isaacs and Sturgis⁴⁰ report but slight response when mucosa and muscularis are fed separately, but Wilkinson⁴¹ found the two equally potent. The potency of various parts of the stomach has been studied, and Meulengracht⁴² summarizes the literature on this point. In very careful experiments he found preparations from the pylorus highly active clinically, while those from the fundus were inert. Material from the cardia is under investigation. Pepsin and rennin activities were considerable in preparations from the fundus and small in those from the cardia and pylorus. Sharp⁴³ found dried defatted duodenum active in pernicious anemia, but Henning and Brugsch⁴⁴ found duodenal preparations inert. The opinions regarding the relative potency of mucosa and muscularis alone vary, probably owing to the technical difficulties in cleanly separating the layers.

Morris and his collaborators⁴⁵ have reported a principle, to which they have given the name "addisin," in normal gastric juice which produces reticulocytosis and a rise in red count and hemoglobin when administered

parenterally in pernicious anemia. Injections of from 10 to 20 cc of normal gastric juice elicit no response, but when from 3 to 5 liters of swine gastric juice is concentrated in vacuo at relatively low temperatures, and injected, a response occurs, which is earlier and more sustained than that occurring with liver extract. As a rise in both red cells and hemoglobin follows, it is probably analogous to that obtained with liver, although the analogy may lie with the response following the administration of arsenic, which has long been known to initiate, but not to maintain, remissions in this disease. The work of Fouts and his co-workers,⁴⁶ however, makes it probable that the large volumes of gastric juice employed contain sufficient amounts of intrinsic and extrinsic factors and that the latter undergoes a digestion during the vacuum distillation generating active material which produces a response analogous to that of liver. These workers found that, if fresh gastric juice from normal individuals was at once chilled and passed through an ultrafilter in the icebox, and the ultrafiltrate was then concentrated in vacuo, no response was obtained on injecting either concentrate or ultrafiltrate alone. If, however, the juice was first stored for two months in the icebox, or first distilled in vacuo and then subjected to ultrafiltration, the ultrafiltrate was active. It is difficult to escape the conclusion that prolonged storage or warming during distillation had permitted a reaction between extrinsic and intrinsic factors to form active material. The fact that addisin is thermolabile also supports this point of view. Morris's suggestion⁴⁷ that polycythemia vera results from an excess of addisin has not been confirmed.

Walden and Clowes⁴⁸ have reported a marked increase in potency of liver extracts incubated with unheated stomach tissue, suggesting that liver contains extrinsic factor which is activated by gastric intrinsic factor, in addition to finished antipernicious anemia material.

Herron and McElroy⁴⁹ have reported a marked increase in the antipernicious anemia potency of liver autolyzed for several days in weak acid, suggesting the presence of both extrinsic and intrinsic factors in liver itself. Castle,⁵⁰ however, has been unable to detect increased potency in either experimental or commercial preparations made in this way.

Of great interest are preliminary reports by Castle⁵¹ that, though mixtures of extrinsic and intrinsic factors are potent when administered orally, there have been no responses observed following parenteral administration.

LIVER THERAPY IN OTHER ANEMIAS

The interaction of extrinsic factor and intrinsic factor administered orally generates antipernicious anemia factor, which is stored in liver and kidney. Addison's anemia may be defined as due to a lack of intrinsic factor,⁵² though dietary extrinsic factor is adequate. In tropical sprue the intrinsic factor may be absent but is

probably usually present, the lack of extrinsic factor in the diet together with a marked impairment in absorption in the intestinal tract being the chief faults. The response to parenteral liver therapy is dramatic.⁵³ Sprue is probably due to a multiple deficiency in which vitamins and iron at times play a part.

That the pernicious anemia factors may play a part in the complex picture of pellagra is probable. Rhoads and Miller⁵⁴ have produced black tongue in dogs with anemia and bone marrow changes closely simulating those of pernicious anemia. The diet was poor in vitamin B₂ (G) and probably in extrinsic factor. Spies⁵⁵ reports clinical improvement following maximal doses of parenteral liver extract in pellagra.

The anemia of pregnancy⁵⁶ is complex, the added needs of the fetus along with a temporary loss of maternal intrinsic factor causes a deficiency of liver material or of iron or both.

Various disturbances of the gastro-intestinal tract,⁵⁷ such as diarrhea or intestinal obstruction, may interfere with the proper absorption of antianemic material, while its storage in the liver may be impaired in cirrhosis.⁵⁸

The anemia of infestation with *Bothriocephalus latus*⁵⁹ has been found to yield to liver therapy without the removal of the worm. This anemia is better interpreted as due to a deficiency than to a hemolytic poison, and the observation⁶⁰ that liver extract protects rabbits from saponin but not from phenylhydrazine anemia can be well interpreted on the probable assumption that liver material is a precursor of red cell stroma.

Secondary anemias of the types that yield to iron have been shown by Murphy⁶¹ to yield more rapidly if parenteral liver extract is also given at weekly intervals.

It is of interest that, although spinal cord involvement is common in Addison's anemia, it is extremely rare in sprue. It is not yet possible to say whether a lack of a single substance is responsible for both spinal cord and blood involvement, but this seems probable. The impression of certain observers that stomach preparations are more effective than liver in the treatment of combined systemic disease is questionable. It is also of interest that liver extract from an untreated patient dying of Addison's anemia was inert.⁶¹ Jacobson⁶² has confirmed this, using his guinea-pig method.

Reimann and Weil⁶³ have recently developed an improved technic in testing for the intrinsic factor, using from 10 to 20 Gm of liver instead of 200 Gm of beefsteak as the source of extrinsic factor.

Edmunds, Brueckner and Fritzell⁶⁴ have shown that a reticulocytosis follows the administration to pigeons

of various liver and stomach preparations, this may prove a useful method of assay of antianemic potency. Miller and Rhoads⁶⁵ have found that swine fed on the Goldberger diet develop the blood picture of pernicious anemia, and that their gastric juice loses both acid and intrinsic factor, and their livers antianemic potency. Salus and Reimann have noted that the gastric juice of patients with subacute combined degeneration but without marked anemia contains Castle's intrinsic factor although no hydrochloric acid is present.⁶⁶

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
HOWARD A. CARTER Secretary

ADLANCO PORTABLE ULTRATHERM ACCEPTABLE

Manufacturer Adlanco X-Ray Corporation, New York

This machine is recommended for medical diathermy, that is, for producing heat within the body tissues.

The Portable Ultratherm is a short wave diathermy machine of the two-tube push-pull oscillating type. The hook-up is laid out simply, all electrical parts are well made, and the workmanship appears satisfactory. The unit is not equipped with a meter, but a small lamp is used to indicate when the patient's circuit is in resonance. The machine is about 18 by 18 by 12 inches in size, weighs about 35 pounds, and is provided with a carrying case.

Under full load this unit was operated for two hours and the temperature of the cabinet and transformer did not rise above the limits of safety previously established by the Council. The wavelength was found to be approximately 6 meters. The input power is about 395 watts. So far as is known, there is

no reliable or acceptable method of measuring the power output of short wave diathermy machines.

In a clinic acceptable to the Council, the machine was tested and the investigator reported that the unit supplied sufficient energy to heat the body tissues whenever such treatment is indicated. The tissue heating effect in the human thigh was investigated. The technique used was that recommended by the manufacturer. Cuff electrodes of pliable metal encased in rubber,

Adlanco Portable Ultratherm

about 20 inches long and 3 inches wide, were used. When applied to the patient, the rubber cuffs are separated from the skin by a thickness of felt and toweling. This technique was used throughout the tests. Thermocouples were introduced into the subcutaneous deep lying tissue (quadriceps extensor). After twenty minutes treatment, operating the machine at the patient's tolerance, the temperature rise (average of eight tests) was observed to be more than that for conventional diathermy.

Burns may be produced by this machine, but, with ordinary care, they may be avoided, their likelihood to occur is much less than with conventional diathermy.

In view of the foregoing report, the Council on Physical Therapy voted to include the Adlanco Portable Ultratherm in its list of accepted apparatus.

Committee on Foods

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION, AND FOR GENERAL PROMOTION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

RAYMOND HERTWIG Secretary

LARSEN'S "FRESHLIKE" APPLESAUCE

Manufacturer—The Larsen Company, Green Bay, Wis.

Description—Canned, peeled, strained apples, cooked in a small amount of water, retaining in high degree the natural mineral and vitamin values.

Manufacture—Matured apples of chosen varieties are peeled (all stem, core material and bruised parts are removed), washed and immersed in a 2 per cent salt solution, after removal from which they are washed to remove the salt, heated to 82 C in closed aluminum kettles with a small amount of water, strained through a paddle type monel metal pureeing machine in an atmosphere of steam, and automatically filled into enamel-lined cans, which are sealed, processed, and quickly cooled.

Analysis (submitted by manufacturer) —	per cent
Moisture	87.9
Total solids	12.1
Ash	0.2
Fat (ether extract)	0.03
Protein (N X 6.25)	0.3
Reducing sugars as invert sugar	6.3
Sucrose	0.7
Crude fiber	0.5
Carbohydrates other than crude fiber (by difference)	11.1

Calories—0.5 per gram 14 per ounce

Claims of Manufacturer—Scientifically prepared to retain in high degree the natural color, flavor, mineral and vitamin values.

CHURCH'S CONCORD GRAPE JUICE

Manufacturer—Church Grape Juice Company, Kennewick Wash.

Description—Bottled, processed Concord grape juice.

Manufacture—Concord grapes grown in company vineyards or under contract are washed and crushed. Stems are removed and the resulting pulp is heated to 70 C. The juice is expressed, heated to 80 C, hermetically sealed in 5 gallon glass demijohns and stored at 7 C for three months. The juice is siphoned off the argols, filtered, heated to 60 C, bottled, and heated for forty-five minutes at 78 C. Aluminum steam jacketed kettles are used. No toxic spray is used in the culture of the grapes.

Analysis (submitted by manufacturer) —	per cent
Moisture	82.2
Ash	0.3
Fat (ether extract)	1.0
Protein (N X 6.25)	0.2
Reducing sugars as invert sugar	16.9
Sucrose	0.0
Total carbohydrates (by difference)	16.9
Titrate acidity as tartaric acid	0.7

Calories—0.8 per gram 23 per ounce

Claims of Manufacturer—Processed Concord grape juice for all table uses.

HAWAIIAN FINEST QUALITY PINEAPPLE JUICE

- 1 AUNT NELLIE'S
- 2 GROSSE POINTE
- 3 JOHNSON'S BESTOVAL BRAND

Distributors—1 Aunt Nellie's Farm Kitchen, Inc., Hartford Wis., and Harrisburg Grocery Company, Harrisburg, Pa. 2 R. Schayowitz & Sons, Detroit. 3 H. A. Johnson Company, Boston and New York.

Packer—Hawaiian Pineapple Company Ltd., San Francisco.

Description—Canned Hawaiian pineapple juice retaining in high degree the natural vitamin content, the same as Dole Hawaiian Finest Quality Pineapple Juice (Unsweetened) (THE JOURNAL, June 3 1933, p. 1769).

SATURDAY, AUGUST 10 1935

ANIMAL VS VEGETABLE PROTEIN

The controversies of the latter part of the last century regarding the importance of protein in the diet were concerned chiefly with the relative importance of the nitrogenous components of the food to the other ingredients ingested. Beginning some thirty years ago with the pioneer work of Osborne and Mendel and of Hopkins, there developed the more modern interpretation of the importance of protein in nutrition. The value of any protein or food or ration in meeting the protein requirement of animals depends on the nature and the amounts of amino acids yielded on hydrolysis. Proteins that are unsatisfactory for nutritive purposes are not toxic or poorly utilized but are lacking in one or more of the so-called essential amino acids, which cannot be synthesized by the animal organism and must therefore be adequately supplied in the diet. The emphasis thus has been transferred from one of quantity of protein in the diet to that of quality of ingested protein.

The development of methods for the preparation of purified proteins and for their analysis for amino acid composition, and the elaboration of procedures for determining the biologic value of proteins,¹ have emphasized the importance of the individual amino acid components of a protein in determining its value in nutrition. Investigators have clearly established that, in general, the proteins of animal origin are superior to the vegetable proteins for purposes of nutrition.

Within recent years, results have been made available on the effects of the prolonged ingestion of proteins of vegetable origin on a variety of functions. Since the diet of the majority of the Chinese people is largely vegetarian, extensive studies were conducted by Wu and his collaborators² at Peiping Union Medical College on the question of vegetarian diets with a laboratory animal

of the omnivorous type. The white rat has proved ideal for this study, the high degree of standardization of the behavior of this rodent, together with the opportunity which the rat affords for the study of successive generations, is of importance. It is obvious that the rate of growth, for example, of rats is not an adequate test of the value of a diet, if the animals used are born of mothers on a good diet and have been nursed by them. The true quality of the diet is revealed only in the offspring of these animals. It might be pointed out, therefore, that the testimony of human vegetarians is worthless, because they were probably not vegetarians during the first part of their lives and they do not carry the test to the second generation.

The results of the studies of Wu and his group clearly demonstrate that animals ingesting a vegetarian ration grow at a slower rate than controls ingesting a mixed diet. Furthermore, the diminished growth rate is accentuated in successive generations. There is no decided difference in life span, however, and in view of the slower rate of growth it follows that the vegetarian rats attain a smaller final body weight than do the control animals. Fertility remains normal, but the ability of the experimental animals to nurse young is quite inferior to that of the rats in the stock colony. The basal metabolism of the vegetarian rats is somewhat lower than that found in the control omnivorous animal. A detailed study has been made of the weights and size of the various organs of rats of different ages on the vegetarian diet. Calculated on the basis of equal body weights, the organs, with the exception of the kidneys, liver, spleen and testes, of the vegetarian rats are heavier and larger than those of the omnivorous rats. The differences are statistically significant. The thyroid gland of the vegetarian rat is about three times heavier than that of the control. Adding iodine to the diet of the former reduces the thyroid to normal size but has no effect on the growth curve or on the weights of other organs. This indicates that the poor growth of the vegetarian rats is not due to the lack of iodine in the diet.

There was little effect of the vegetarian diet, continued for many generations, on the gross physical characteristics or on the general health of the animal. It is of some significance that the vegetarian rats may grow to maturity and reproduce, even when continued for several generations on the same diet, without any sign of abnormality except the lowered growth rate. A diet which is so deficient as to be inadequate for growth and reproduction is easily recognized by its effect, it must be changed to a better one or the race will perish. In either case no weaklings remain. However, a diet that is slightly deficient and yet suffices to propagate the race after a fashion may never arouse suspicion and hence continues to exert its insidious effects. This is true not only of a strictly vegetarian ration but of any slightly deficient diet.

UNDERNUTRITION

Undernutrition may be arbitrarily defined as a condition characterized by a deviation of body weight amounting to from 10 to 15 per cent below the statistical ideal for a given age, sex and height. Lusk¹ some time ago reviewed the large amount of information available regarding the detrimental effects of undernourishment. Among the unfavorable effects are general weakness and tiredness, physical and mental incompetence and increased susceptibility to disease. At present the so-called acute and chronic forms of undernutrition are recognized. It is generally conceded that the weight loss in acute undernutrition has a direct relation to a period of inadequate food intake, resulting from either a qualitative or a quantitative deficiency of the diet. This may occur during economic crises, as in wartime or in droughts, or it may occur as a result of acute pathologic processes. Chronic undernutrition, on the other hand, is regarded as a different type of phenomenon, the etiology of which is not clearly understood. The various explanatory hypotheses advanced include those which postulate abnormal functioning of the endocrine glands, peculiarities of the nervous system, chronically inadequate dietaries, and anomalies of metabolism. Although there is some evidence for the first of these hypotheses, the current opinion appears to favor the view that they are of secondary importance and perhaps a result of disturbances initiated by one or both of the latter two circumstances. The importance of an adequate dietary in the correction of undernutrition is well known. A short time ago further evidence for the favorable therapeutic value of the dietary procedure was reported.² A group of twenty-one undernourished office patients given a diet containing adequate amounts of the known dietary essentials and supplying a positive energy balance showed consistent body weight responses. During an average period of eleven weeks the subjects showed an average increase in weight of 17 per cent, or $1\frac{1}{10}$ pounds (770 Gm) per week. Similar results were obtained on a group of eighteen hospital patients, their average body weight increase was 13 per cent in a period of five weeks. In addition, many diverse symptoms disappeared, the patients expressed a feeling of well being, and they became more resistant to fatigue and to infection.

Studies on the metabolism of this series of patients, which have been reported recently,³ lend further evidence against the view that anomalies of metabolism are major factors in the production of chronic undernutrition. The average basal metabolic rate of the series of eighteen hospital patients before treatment was a minus 2, a value not unlike one that might be obtained from a similar series of normal subjects.

After the period of five weeks on the high caloric diet, no significant change in the basal rate occurred, the average value being a minus 6. However, as might be expected in view of the fact that the total heat production of undernourished individuals is low, there was some increase in this value. Simultaneous studies of the nitrogen metabolism and of the efficiency of digestion of these subjects revealed no abnormality in the utilization of nitrogen or in the digestion and absorption of the dietary constituents, either before or during treatment. Indeed, the figures relating total weight of food ingested to the total weight of feces excreted indicated that 92 per cent of the food consumed was digested and absorbed during the period of treatment. This value is well within the recognized limits for normal subjects ingesting an ordinary mixed diet. Furthermore, an even more efficient digestion of foods (94 per cent) was found in subjects consuming the higher caloric diets than in those provided a ration of somewhat lower caloric content. Therefore it appears that the gastro-intestinal tracts of these undernourished subjects were not inferior to those of normal individuals and that their undernutrition was not the result of anomalies of metabolism.

The hypothesis that chronic undernutrition is caused by inadequate food intake apparently alone remains unchallenged by convincing contradictory evidence. Whether or not this thesis will stand the test of time and, if so, the ultimate reason for the consumption of subnormal amounts of food, remain to be determined.

INHIBITION OF LEUKOPOIESIS BY
CERTAIN DRUGS

Recognition of the relationship of the administration of certain compounds, notably amidopyrine, to the occurrence of granulocytopenia¹ has led to studies of the effects of such substances on circulating granulocytes. The results of animal experiments have for the most part proved equivocal. Administration of drugs suspected of being implicated as etiologic factors has had little detectable effect in most cases, even when the substances were given in large amounts. This is not surprising in view of the infrequency with which granulocytopenia occurs clinically, despite the large quantities of amidopyrine and similar drugs employed. The attention of investigators has therefore been diverted from study of the circulating blood to observation of changes in the bone marrow.

Miller² of the Rockefeller Institute administered amidopyrine in daily doses of 0.3 Gm per kilogram of body weight by mouth to sixteen dogs. With this large dose no marked decrease in circulating granulocytes occurred, even when the treatment was continued

² Miller, D. K. *Histological Changes in the Bone Marrow of the Dog Following Amidopyrine Administration*. *Science* 80: 320 (Oct. 5) 1934.

for four weeks or more. There was a decrease in the number of circulating erythrocytes of varying degree. Despite the absence of a notable effect on the white cells of the circulating blood, striking changes were noted in the bone marrow. The hematopoietic elements failed to mature and the number of young, relatively undifferentiated cells was increased, the granulocytes were decreased in number, sometimes almost to zero. In the more advanced cases the orderly arrangement of the bone marrow into hematopoietic islands had been disturbed. It appears, therefore, that marked changes may take place in the bone marrow with little or no reflection of these alterations in the formed elements of the circulating blood.

Further evidence as to the mechanism of the action of certain cyclic drugs in the production of granulocytopenia has been presented by Climenko,³ working at Cornell University. The latter investigator determined the effect of administering to rabbits amidopyrine, antipyrine, 2,4-dinitrophenol, phenylhydrazine hydrochloride, catechol and orthoquinone on the response of the leukogenic tissues to stimulation by nucleic acid. Normally the injection of this substance produces a sharp rise in the number of circulating leukocytes. It was found that, after the administration of any of the cyclic compounds mentioned, the ability of the hematopoietic tissues to respond to this stimulus was lost long before any change could be observed in the cellular constituents of the peripheral circulation. A normal rabbit with a white blood count varying between 8,100 and 10,400 responded to the intramuscular injection of 5 mg of nucleic acid per kilogram of body weight with a rise in the count to 15,100. Beginning ten days later this animal received daily 0.2 Gm of amidopyrine per kilogram by mouth for eighteen days. At the end of this time a similar dose of nucleic acid caused no detectable increase in the leukocyte count of the peripheral blood. Similar reactions were obtained with the other drugs, phenylhydrazine being the most potent and antipyrine the least active in this respect. Changes in the bone marrow were observed similar to those reported by Miller. Dinitrophenol required a dosage of 20 mg per kilogram to inhibit leukogenesis; in this dosage a preliminary increase occurred in the percentage of juvenile cells in the circulation, this reaction disappeared in a few days while the drug was being administered. Shortly after this the administration of nucleic acid failed to evoke a response. Information is not yet available as to how long the refractoriness to stimulation by nucleic acid persists after administration of any of these drugs is stopped.

Thus it appears that certain cyclic compounds may readily cause marked changes in the bone marrow without significant alteration in the formed elements of the blood. Whether or not this occurs in human beings

as readily as in animals is not known, it may be that suppression of the bone marrow occurs more frequently than is commonly believed and that untoward effects may arise when concomitant infection or some other factor increases the physiologic demand for circulating granulocytes. Further study possibly will eliminate the uncertainty entailed by the commonly accepted thesis that the production of granulocytopenia by a drug depends on the presence of "hypersensitivity" in the person receiving the drug.

Current Comment

AURICULAR FIBRILLATION AND RHEUMATIC HEART DISEASE

De Graff and Lingg¹ have recently investigated the frequency and influence of auricular fibrillation on the course of rheumatic heart disease. The report is based on the records of 644 deceased patients. The type of valvular lesion seemed to have some effect on the incidence of auricular fibrillation, the highest incidence having been found among patients with mitral stenosis. The percentage of men and women with rheumatic heart disease who developed fibrillation was about the same. Of the total number studied, 42.8 per cent developed auricular fibrillation. There was no evidence that fibrillation per se determines prognosis or life expectancy. It was demonstrated, however, that fibrillation is usually a late manifestation in rheumatic heart disease and that it is most commonly observed in the relatively long standing cases. There was no correlation between the age when patients first acquired rheumatic fever and the subsequent development of auricular fibrillation. Children who were attacked by rheumatic fever in the first decade of life were as likely to develop this arrhythmia as patients affected later in life, provided the children lived long enough. The longer the disease lasted, the greater were the chances that patients would develop the irregularity. The reason for the short average duration of life after the establishment of fibrillation is therefore obvious.

OXALIC ACID AND CALCIUM UTILIZATION

In a recent editorial in *THE JOURNAL*,¹ attention was called to the ubiquitous distribution of oxalic acid and its salts among natural food products. The leafy vegetables are particularly rich in these substances. Despite the known toxicity of oxalic acid, the quantities ordinarily ingested with these food materials are too small to cause apprehension. Aside from this feature of its biochemistry, oxalic acid might reasonably influence adversely the utilization of food calcium through the formation of the highly insoluble calcium oxalate. This question is worthy of careful study, particularly in the light of the repeated assertions that the calcium of leafy

³ Climenko, D. R. Inhibition of Leukogenic Activity in the Rabbit by Certain Cyclic Compounds. *Proc. Soc. Exper. Biol. & Med.* 32: 823 (March) 1935.

¹ De Graff, A. C. and Lingg, Claire. The Course of Rheumatic Heart Disease in Adults. III. The Influence of Auricular Fibrillation on the Course of Rheumatic Heart Disease, *Am. Heart J.* 10: 630 (June) 1935.

¹ Oxalic Acid in Metabolism editorial, *J. A. M. A.* 103: 1152 (Oct. 13) 1934.

vegetables is less readily available to man than is that ingested in other forms. A recent note by Kohman and Sanborn² describes some timely experimental studies bearing directly on this question. Although, in their experience, some calcium for the formation of bone is provided by the insoluble calcium oxalate, this salt is not a readily available source of lime. Furthermore, it was found that, if soluble oxalates are present in the food, the utilization of calcium from a known available source is interfered with. The administration of soluble oxalate in nontoxic doses was shown to increase the loss of calcium from the body. It appears then that oxalic acid can interfere not only with the absorption of calcium from the intestine but also with the retention of this element once it has been taken into the body. When further investigation has made these biochemical relationships more definite, there may be presented the nutritional paradox of certain natural foods relatively rich in calcium with other features that actively interfere with its utilization by the organism.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

DISTRICT OF COLUMBIA

Medical Bills in Congress—S 1016 has been reported to the House, proposing to empower the health officer of the District of Columbia to authorize the opening of graves, and the disinterment and reinterment of dead bodies, in cases in which death has been caused by certain contagious diseases. S 2013 has been reported to the House, providing for the issuance of a license to practice the healing art in the District of Columbia to Dr. Pak Chue Chan. S 2939 has been reported to the House, providing for the issuance of a license to practice the healing art in the District of Columbia to Dr. Ronald A. Cox. H R. 8437 has been reported to the House, providing for the issuance of a license to practice the healing art in the District of Columbia to Dr. Arthur B. Walker. S 3284, introduced by Senator Copeland, New York, proposes to provide for the issuance of a license to practice the healing art in the District of Columbia to Dr. Dexter P. Reynolds.

FLORIDA

Society News—Speakers before the Dade County Medical Association, July 5, were Drs. Elmer H. Adkins and Lee W. Elgin, Miami Beach, on "Rectal Abscesses and Fistulas" and "Trichomoniasis of the Male Urethra and Prostate," respectively. Dr. Emil Novak, Baltimore, spoke on a gynecologic topic before the Orange County Medical Society in Orlando, June 29. Dr. Wilfred McL. Shaw, Jacksonville, was elected president of the Florida State Radiological Society at its recent annual meeting in Ocala. Dr. Frazier J. Payton, Miami Beach, vice president, and Dr. Gerard Raap, Miami, secretary. The next annual meeting of the association will be in May 1936 at Miami.

"Ice Memorial Week" Commemorates Physician.—The governor has proclaimed the week of August 11-17 the "Dr. John Gorrie Ice Memorial Week," in honor of the physician who invented artificial refrigeration. Dr. Gorrie, who was born in Charleston, S. C., Oct. 3, 1803, went to Apalachicola in 1833 and practiced there until his death in 1855. In 1847-1848, while preparing a series of papers for the London *Lancet* on "Equilibrium of Temperature as a Cure for Pulmonary Consumption," one of his chemical experiments on air cooling resulted in the making of artificial ice. He immediately set about perfecting this idea with the result that the first ice machine ever made and operated was patented in 1850. A year

ago the John Gorrie Memorial Foundation was chartered in Florida to provide hospitalization to needy persons in the town where Dr. Gorrie perfected his invention and to carry on a nation-wide drive against cancer. The ice manufacturers of Florida will begin to collect funds to establish an endowment for the foundation during "ice memorial week," during which they will contribute 14 per cent of their income each day. The Florida State Medical Association, several members of which are on the foundation's board of directors, endorsed the memorial at its recent annual meeting in Ocala.

GEORGIA

Society News—Dr. William W. Anderson, Atlanta, addressed the Cobb County Medical Society at Marietta, June 4, on "Digestive Disturbances of the Season in Children," and Dr. George F. Eubanks, Jr., "Surgical Treatment."—Papers were presented before the Georgia Medical Society, Savannah, at its meeting, June 11, by Drs. Marion K. King on "Treatment of Fracture Below the Knee with Walking Plaster Cast," and Shelton P. Sanford, "Vascular Lesions of the Lung Simulating Pneumonia."—Dr. Thomas P. Goodwyn, Atlanta, discussed fractures before the Spalding County Medical Society at Griffin, June 18. At a meeting of the Thomas County Medical Society in Thomasville, June 19, Dr. Ernest F. Wahl, Thomasville, among others, discussed "Pneumothorax in the Treatment of Pulmonary Tuberculosis."—The Ware County Medical Society was addressed in Waycross, July 3, among others, by Dr. Thomas J. Ferrell on "The Mortality in Appendicitis."

ILLINOIS

Funds for Work on Trachoma—The state department of health announces an appropriation of \$45,000 to extend for two years its work on trachoma among the indigent of the southern fourteen counties of Illinois, which has been in progress for more than a year under the supervision of Dr. Harry S. Gradle, Chicago. The state department of public welfare and the Illinois Society for the Prevention of Blindness are cooperating in the project, which includes the operation of outpatient clinics for treatment and preventive work.

Chicago

Study of Maternal Mortality—About 600 cases have been studied to date in a survey of maternal mortality being conducted by the maternal welfare committee of the Chicago Gynecological Society. It is hoped to continue the study until data on about 1,000 cases have been accumulated. Sixty-eight physicians compose the committee, which represents the seventy-six hospitals in Chicago doing obstetric work. The executive committee has nine members, five appointed by the society, three elected from the membership and the president of the board of health; this committee outlines the policies and methods of procedure. All information is obtained by mail, in 1933 all but one case report blank was returned, and in 1934 all but twelve. Information for 1934 is still being received, however. The board of health supplies the secretary with a copy of any death certificate in which pregnancy is mentioned. The secretary in turn mails a form to the hospital representative, who fills out the blank and returns it to the secretary. In case the woman dies at home, the form is mailed to the attending physician.

INDIANA

Personal—Purdue University conferred the honorary degree of doctor of laws on Dr. Richard B. Wetherill, Lafayette, at the commencement, June 11. Dr. Arthur J. Steffen, Somerset, has been appointed health commissioner of Wabash County.

Ravdin Medal Awarded.—Dr. Edward L. Efroymson, Indianapolis, was awarded the Ravdin Medal of the Indiana University School of Medicine recently. The medal is given annually by Dr. Marcus Ravdin, Evansville, to the medical school senior who makes the highest scholastic average in the course.

Early Medical Publications—An exhibit of early medical publications was held recently at the Indiana University School of Medicine library and museum. Included among the works on display were the *Indiana Journal of Medicine and Surgery*, considered to be the second purely local medical journal in the state, the *Western Quarterly Reporter of Medicine, Surgery and the Natural Sciences*, the first medical journal published west of the Allegheny mountains, which published six issues at Cincinnati in 1822-1823, the *Medical Repository*, started in 1797 and continued for twenty-three volumes, and the first volume of the *New England Journal of Medicine and Surgery* of 1812, which has been published continuously with a few changes of name and form for 123 years.

² Kohman, E. F. and Sanborn, N. H. J. Indust. & Engin. Chem. 27: 732 (June) 1935.

IOWA

Changes in Health Regulations—Several changes in the rules and regulations of the state board of health were approved at a meeting, July 9. Notable among these changes are those affecting scarlet fever, for which the quarantine period has been reduced from twenty-eight to twenty-one days from the date of report of a mild, uncomplicated case to the local department of health and the state board of health. The minimum isolation period may be extended if the patient develops a complication, if abnormal discharges continue or if others in the home become ill. In any case, after removal of the quarantine notice from the house, the patient should remain at home one additional week before returning to school or attending public gatherings. Psittacosis has been made a reportable disease, and typhoid made placardable from the onset of illness to the time of receipt of laboratory reports indicating freedom of bodily discharges from the presence of typhoid germs. The period of placard and isolation for measles and chickenpox is reduced, in the uncomplicated case, from fourteen to ten days.

KENTUCKY

Personal—Dr. Ollie M. Goodloe, Paducah, has been appointed health officer of Mason County with headquarters at Maysville and Dr. Aubrey Y. Covington, of Union County, with headquarters at Morganfield.—Dr. Eugene W. Demaree, formerly of Ashland, has returned from five years' service in Korea and will take up practice in Ashland.—Dr. Ernest B. Bradley, Lexington, was honored at a dinner given by the Fayette County Medical Society at the Lexington Country Club June 27 in recognition of his recent election to the presidency of the American College of Physicians. Informal addresses were made by Drs. Chauncey W. Dowden and William Barnett Owen, Louisville, and Dr. Bradley. Dr. Harry G. Herring, Lexington, president of the county society, presided. Dr. Bradley will take office in 1936.

MAINE

Radium Exempted from Taxation—The legislature of Maine, during its 1935 session enacted a law exempting radium used in the practice of medicine from taxation.

MINNESOTA

Medal to Dr. Hanson—Dr. Adolph M. Hanson, Faribault, who prepared active thymus and pineal extracts for experiments on biologic effects of the extracts on rats, was awarded the medal of the Southern Minnesota Medical Association, presented annually during the meeting of the Minnesota State Medical Association, for his exhibit at the state meeting in Minneapolis, June 24-26. Dr. Hanson, who graduated from Northwestern University Medical School, Chicago, is now engaged in private practice.

Dr. Dunn Accepts Washington Post—Dr. Halbert L. Dunn, professor of biometry, University of Minnesota Graduate School of Medicine, Minneapolis, and director of the University of Minnesota Hospitals, Minneapolis, has resigned to become chief statistician of vital statistics, division of the bureau of census U. S. Department of Commerce, Washington, D. C. Dr. Dunn is 39 years of age and a graduate of the University of Minnesota Medical School, class of 1922. The new appointment was effective July 1.

Investigation of Typhoid Outbreak—Twenty thousand dollars has been appropriated by the state executive council to conduct a survey of the city water systems of Minneapolis and St. Paul to determine the source of an outbreak of typhoid in which 111 cases had been reported up to July 22. About 100 cases had been recorded with the city health department of Minneapolis between May 25 and July 15 (THE JOURNAL, August 3, p. 377). Specimens taken from the cities' water supplies were found to be slightly contaminated. A staff of investigators will be employed to cooperate with the city health departments in the survey, which will last six months, it was reported.

NEW JERSEY

State Board Election—The Board of Medical Examiners of New Jersey at its annual meeting July 20 elected Dr. Harry H. Satchwell, Irvington, president, Dr. Arthur W. Belting, Trenton, secretary, and R. M. Colborn, D. O., Newark, treasurer.

Art and Hobby Exhibit—One hundred and fifty-two items were shown in the art and hobby exhibit at the annual session of the Medical Society of New Jersey. The exhibit was managed by the Woman's Auxiliary under the chairmanship of Mrs. Harold D. Corbuser, Plainfield. Among the articles displayed were paintings and photographs, sculptures, hand-made jewelry, ancient Peruvian textiles, antique instruments, Indian

relics, a model engine and a collection of arms. Physicians and members of their families were eligible to enter their hobbies.

Society News—Dr. George G. Ornstein, New York, was the guest speaker at the May meeting of the Bergen County Medical Society at Bergen Pines, on "Pulmonary Tuberculosis, with Special Emphasis on the Childhood Type." The society's spring festival was celebrated in the afternoon preceding the scientific meeting, with baseball, trap shooting, horseshoe pitching and archery.—Dr. Francis Ashley Faught, Philadelphia, addressed the Cumberland County Medical Society at the home of Dr. Reba Lloyd, Bridgeton, July 9, on "Low Blood Pressure and Its Significance."

Safety Council Awards Medal to Physician—The National Safety Council has awarded to Dr. Benjamin A. Treiber, Trenton, the President's Medal for saving a human life through the use of the prone pressure method of resuscitation. Last February Dr. Treiber, responding to a telephone call, found seven persons in a household overcome by gas from a coal heater. He opened the windows, called the police for assistance, and directed the police and firemen in applying artificial respiration for an hour and a half until six of the victims recovered. Dr. Treiber is the first physician to receive the award.

NEW YORK

State-Owned Spa at Saratoga Springs Dedicated—Saratoga Spa, with new buildings erected by the state at a cost of \$4,500,000, was formally opened July 26. Governor Lehman in his address outlined the history of the state's interest in the springs of Saratoga, which began in 1910. At that time the springs were being exhausted by commercial exploitation. Between 1910 and 1912 the state acquired 163 springs and about 1,000 acres of land and built two buildings, an investment of \$4,000,000. Of the funds for the present development, \$3,200,000 was a loan from the Reconstruction Finance Corporation. In the group of buildings some of which are not yet completed, are the Hall of Springs, the central structure in which there are marble fountains serving the three principal waters of the spa, the Simon Baruch Research Laboratory, the Roosevelt Baths, the state bottling works for the water that is distributed through commercial firms, and the Gideon Putnam Hotel for patients and their families. In the Baruch Laboratory are physicians' offices and examination rooms, experimental baths for clinical study, a museum, a mineral water laboratory and an auditorium with a capacity of 600. The medical director is Dr. Walter S. McClellan. The Gideon Putnam Hotel takes its name from the man who is said to have built in 1802 the first hotel at the resort. Besides the governor, the speakers were George Foster Peabody, a member of the original committee appointed to buy the springs and land and Dr. Frederic E. Sondern, New York, president of the Medical Society of the State of New York. The spa will be operated under the Saratoga Springs Authority, of which Pierrepont B. Noyes, New York, is president.

New York City

Twenty Thousand Children Immunized—A ten weeks campaign for immunization of children against diphtheria, conducted by the department of health in Brooklyn and Manhattan, resulted in the protection of 14,591 in Brooklyn and 7,346 in Manhattan. The board of education, medical societies, Catholic school boards, and social and civic organizations of the two boroughs cooperated, and school children acted as special health officers to round up children under 6 years of age and have their parents sign immunization requests.

The New Floating Hospital—A new all steel hospital ship completed this spring was placed in operation July 1 by St. John's Guild, which has provided free excursion trips for poor children for sixty-seven years. The new boat, which is the fourth the guild has used, can accommodate about 1,500 persons and has water-tight compartments. Its facilities include a clinic where physicians and nurses are on duty, day nursery, milk room, shower baths, rooms for treatment, play rooms, and a motion picture theater with a capacity of 1,000. It makes six trips a week, three from an East River pier and three from Brooklyn.

New Health Center—A new district health center to be built under a program planned by the department of health was begun with the laying of the cornerstone, June 17, in the Mott Haven district of the Bronx. The Public Works Administration provided funds for seven of these centers, of which the Mott Haven unit will be the first. Dr. John L. Rice, health commissioner, pointed out that the general death rate as well as the rates for infant mortality and tuberculosis were

higher in that district than for the Bronx as a whole. The program to be conducted will be educational rather than clinical, it was said.

Gifts to New York University—Among gifts to New York University since March for support of work in the medical college are the following:

Carnegie Corporation of New York, \$8 750
Rockefeller Foundation \$1,000 for salaries of visiting teachers
Georgia Warm Springs Foundation for research on poliomyelitis under Dr. William H. Park other donors \$2 160 47
Bernard M. Baruch \$3 092 93 for studies on pneumonia under Dr. Milton B. Rosenberg
International Cancer Research Foundation \$1 500 for research in cancer under Robert Chambers Ph D Washington Square College
New York University
E. R. Squibb and Sons \$1,250 for a fellowship in the department of surgery
Mrs. Alfred F. Hess, \$1 000 to establish the Alfred F. Hess Nutrition Fund under direction of Dr. Jacques M. Lewis

Opening for Psychiatrist—The Municipal Civil Service Commission of New York announces an examination for the position of director of the division of psychiatry in the department of hospitals (Bellevue Hospital), October 16-19. The examination is open to all citizens of the United States, but the appointee must reside in New York after he has accepted the position. Applicants must not be more than 55 years old and five years of which must have been as a member of the clinical staff of a recognized mental hospital or as a member of the psychiatric department of a general hospital with an organized psychiatric department. Applications will be received up to October 4. Full information may be obtained from the commission, of which William H. Allen is secretary, room 1400, Municipal Building, Center and Chambers streets, Manhattan.

OHIO

University News—A portrait of the late Dr. John Eaton Darby for many years professor of materia medica and therapeutics, was recently presented to the Western Reserve University School of Medicine by Dr. Darby's son, Dr. John Charles Darby. Dr. Darby died in 1918. Dr. Howard T. Karsner, professor of pathology at Western Reserve, was recently elected to membership in the French Association for the Study of Cancer.

Society News—The eighth district of the Ohio State Medical Association held its spring meeting at Rocky Glen Sanatorium, McConnsville, June 20. Speakers were:

Dr. William E. Lower Cleveland Management of Benign Prostatic Hypertrophy
Dr. Jonathan Forman Columbus Allergy in General Practice.
Dr. Willard Van Hazel, Chicago, Treatment of Empyema with Special Reference to the Chronic Case
Dr. Moses E. Bland Cleveland Peptic Ulcer and Its Surgical Management
Dr. Allen A. Tombaugh McConnsville Collapse Therapy of the Lungs

Typhoid Outbreak Caused by Carrier—Thirty-eight cases of typhoid in persons who attended a social occasion in St. Marys, May 12, have been traced to food prepared by the hostess, who was a carrier. About twenty cases occurred in St. Marys, and the remainder were in guests from other towns. Three were contact cases. The woman gave a history of having had "undulant fever" in 1930 and gallbladder infection twenty years before, two of her children had had typhoid. The facts that typhoid developed only in persons who attended the party and ate chicken salad sandwiches and that the woman who prepared the salad was found to be a carrier substantiated the diagnosis and the source of the outbreak, the state health department concluded. The department's report says that none of the cases had been reported and the state's first knowledge of the outbreak came when several specimens of blood were sent to the laboratory for Widal tests.

PENNSYLVANIA

Society News—Dr. George E. Pfahler, Philadelphia, addressed the Schuylkill County Medical Society, Shenandoah in June, on diagnosis and treatment of cancer. Dr. Richard A. Kern, Philadelphia, addressed the Lehigh County Medical Society, Allentown, July 9, on clinical allergy. Dr. Walter C. Alvarez, Rochester, Minn., addressed the Lehigh Valley Medical Association at its annual meeting at Pocono Manor, July 15, on "Some Useful Tricks in the Treatment of Gastro-Intestinal Disease." Dr. Herbert B. Gibby, Wilkes-Barre, also spoke on "Duty of Individual Physicians to Organized Medicine." Members of the staff of the Torrance State Hospital presented the program of the Westmoreland County Medical Society at the hospital July 18, as follows: Drs. John I. Wiseman, Sterilization; James M. Henninger, Results of Treatment of General Paralysis with Malarial Inoculation at This

Hospital" and E. M. L. Burchard, Ph D, "A Comparative Study of Body Types and Psychoses."—Drs. J. Allen Jackson, medical superintendent, and Peter O. Kwitrovich, of the staff of the Danville State Hospital, addressed the Chester County Medical Society, Chester, June 18, on practical phases of mental hygiene and on the use of atropine in treatment of the parkinsonian syndrome following encephalitis, respectively.

TEXAS

Society News—Drs. Elliott M. Mendenhall and Oscar M. Marchman, among others, addressed the Dallas County Medical Society, June 13, on "Artificial Pneumothorax in Treatment of Lobar Pneumonia" and "Emergency Tracheotomy," respectively. Speakers at a meeting of the Twelfth District Medical Society at Cameron, July 9 included Drs. Ross B. Trigg, Fort Worth, on Compression Fractures of the Body of the Vertebrae; Monroe C. Sapp, Cameron, "Burns, with Special Reference to Burn Toxins;" and Charles M. Simpson, Temple, "Carcinoma of the Prostate."

VIRGINIA

Personal—Dr. William Tate Graham, Richmond, received the honorary degree of doctor of science at the commencement of Hampden-Sydney College in June. The University of North Carolina conferred an honorary degree on Dr. James K. Hall, Richmond, at the June commencement. Dr. William B. Porter, professor of medicine, Medical College of Virginia, Richmond, is studying for two months in Puerto Rico the adjustment mechanisms occurring in the circulatory apparatus in chronic anemias associated with parasitic infections. He will give a series of lectures and clinics while on the island.

Graduate Courses in Pediatrics—Dr. George M. Lyon, Huntington W. Va., gave two graduate courses in pediatrics during July under the auspices of the department of clinical and medical education of the Medical Society of Virginia. The first was at Nassawadox, July 8-19, in cooperation with the medical societies of Northampton and Accomac Counties. The second at Norfolk, July 22-August 2, in cooperation with the Norfolk County Medical Society. Dr. Samuel F. Ravenel, Greensboro, N. C., gave a similar course in Christiansburg, beginning June 19 with meetings twice a week for five weeks, under the auspices of the Montgomery County Medical Society.

WEST VIRGINIA

New Tumor Clinic—Davis Memorial Hospital, Elkins, marked the opening of a new tumor clinic, July 10, with a cancer symposium. The following guests made addresses:

Dr. Max Culler Chicago The Tumor Clinic A Progressive Step in Modern Hospital Organization
Dr. Charles F. Geschickter Baltimore Tumors of the Breast
Dr. Robert Denison Harrisburg Pa. Tumors of the Lungs
Dr. Joseph Colt Bloodgood and Leopold Clarence Cohn, Baltimore Benign Breast Lesions with Special Consideration of Borderline Tumors
Dr. Louis M. Rosenthal Chicago Recent Progress in Radiation Treatment of Cancer
Dr. Benjamin Rice Shore Jr. New York, Care and Cure of Cancer Patients

At a banquet in the evening Dr. William S. Fulton, Wheeling was toastmaster and Dr. George T. Pack, New York, spoke on "Neoplasms of the Gastro-Intestinal Tract."

WYOMING

State Medical Meeting—The thirty-second annual meeting of the Wyoming State Medical Society will be held in Lander August 12-13. The scientific program will be as follows:

Dr. Leonard Freeman Denver Gastric and Intestinal Spasms Their Relation to Surgery
Dr. Henry W. Meyerding Rochester Minn. Dupuytren's Contracture
Dr. Emerson F. Root, Salt Lake City Treatment of Cholecystitis
Dr. Robert T. Jellison Salt Lake City John W. Ames and William Bernard Yegge, Denver and R. Carlton Trueblood Cody Symposium on Pneumonia
Dr. Peter M. Schunk, Sheridan Tetanus Treatment by Serum Intra-cranially
Dr. Reuben J. Boesel Cheyenne Value of Proctology in General Medicine
Dr. Homer R. Lathrop Casper Fractured Femurs
Dr. Louis G. Booth Sheridan Torision of the Spermathe Cord

A golf tournament will be held in two parts, Monday and Tuesday mornings. There will be a clinic dealing with feeble-mindedness and epilepsy at the Wyoming State Training School Monday morning and one on trachoma at the Shoshone Indian Hospital Tuesday. Dr. Herbert L. Harvey, Casper, is president and Dr. Joseph L. Wicks, Evanston, president-elect.

GENERAL

Society Changes Name—The American Federation of Organizations for the Hard of Hearing has changed its name to the American Society for the Hard of Hearing. At the annual conference in Cincinnati, June 3, Dr. Frederick N. Sperry, New Haven, Conn., was elected president. The next conference will be held in Boston, May 26-30, 1936.

Section Appointments—At the recent meeting of the Section on Obstetrics and Gynecology of the American Medical Association at Atlantic City, the following appointments were made: Drs. Fred L. Adair, Chicago, Robert D. Mussey, Rochester, Minn., and Everett D. Plass, Iowa City, to represent the section on the American Board of Obstetrics and Gynecology, and Drs. James R. Miller, Hartford, Conn., Mussey and Plass as representatives on the American Committee on Maternal Welfare.

Study of Fireworks Accidents—The American Museum of Safety has undertaken a nation-wide study of fireworks accidents under the direction of Dr. Leland E. Cofer, New York. The study will seek to ascertain how serious the hazard is, which items of fireworks are involved in most accidents, the effect of prohibitory legislation and the sources of the fireworks that cause accidents. The leading manufacturers of fireworks through Pyrotechnic Industries, Inc., have made a grant to the Museum of Safety and have agreed in advance to take steps to eliminate the elements in fireworks responsible for serious hazards, it was announced. The study was undertaken as a result of a study made by the National Society for the Prevention of Blindness, which found that twenty-nine persons died and more than 3,000 were injured in fireworks accidents in 1934. The organization plans to interview every person injured this year and obtain details of the accidents from him or from the physician or hospital that treated him.

Award in Honor of Theobald Smith—At the summer meeting of the American Association for the Advancement of Science in Minneapolis, the Theobald Smith Award in Medical Sciences was established by Eli Lilly & Co., Indianapolis. The new award will be \$1,000 and a bronze medal, which will be given yearly for "demonstrated research in the field of the medical sciences, taking into consideration independence of thought and originality." Fellows of the association are to submit to the permanent secretary's office in Washington, D. C., the name of a proposed recipient with full information concerning his personality, training and research work. Any investigator who is less than 35 years old on January 1 of the year in which the award is to be made is eligible. Nominations must be received before May 1 each year. The president of the association and four fellows will be the committee of award. The name of the winner will be announced at the summer meeting, and the presentation will be made at the winter meeting of the association.

Change in Status of Licensure—The Wisconsin State Board of Medical Examiners reports the following actions taken at a meeting June 24-28:

Dr. Clayton Eugene May, Minneapolis, Ill., license revoked on reading of his court record for reason of harboring and caring for one John Dillinger.

Dr. William Jerome E. Clancy, Indian Hill, Ohio, license revoked on reading of court record for reason of taking undue liberties with a minor.

At a meeting of the Indiana State Board of Medical Registration and Examination, July 9, the following action was taken:

Dr. Benjamin F. Patton, Terre Haute, license revoked for violation of the Harrison Narcotic Act. Now in federal prison at Leavenworth.

Dr. Frederick J. Freshley, Plainville, license revoked for conviction of automobile banditry. In state prison at Michigan City.

Dr. Hugh Smith Detchon, Victor, Iowa, license revoked for attempted criminal operation. In Iowa State Prison.

The Massachusetts Board of Registration in Medicine announces the following action:

Dr. Eli Silverman, Boston, license restored July 1.

The Kansas Board of Registration in Medicine announces the following action:

Dr. John F. Northrup, Topeka, license reinstated June 18.

The North Dakota State Board of Medical Examiners reports the following action taken July 5:

License of Patrick E. Shortt, Bowdle, S. D., revoked because he obtained restoration of a license previously revoked by making false and unreliable statements.

Society News—Dr. Raymond R. Squier, New York, has been appointed executive secretary of the National Committee on Maternal Health, which has headquarters in the building of the New York Academy of Medicine. Dr. Robert L. Dickinson, New York, is chairman of the executive committee and Dr. Haven Emerson, New York, chairman of the board of

directors.—Dr. Gilbert J. Thomas, Minneapolis, was chosen president-elect of the American Urological Association at the annual meeting in San Francisco, June 25-28. Dr. George G. Smith, Boston, was installed as president, and Dr. Clyde L. Deming, New Haven, Conn., was elected secretary. Dr. Hugh H. Young, Baltimore, delivered the Ramon Gutierrez Lecture on "Abnormalities and Plastic Surgery of the Lower Urogenital Tract," and Dr. Luigi Caporale, Turin, Italy, was a guest speaker, on "Segmental Peridural Anesthesia."—The twenty-first National Recreation Congress will be held in Chicago, September 30-October 4, at the Sherman Hotel.—The first annual session of the Tennessee Valley Medical Association, made up of physicians of eastern Kentucky and Tennessee, western Virginia and North Carolina, and parts of Alabama and Georgia, was held, June 26-27, in Knoxville, Tenn. Dr. Ernest R. Zemp, Knoxville, was made president, and Dr. Tom R. Barry, Knoxville, president-elect. Drs. Ancil A. Richardson, Williamsburg, Ky., Glenn T. Foust, Norton, Va., and James Frank Pate, Canton, N. C., were elected vice presidents, and Dr. Jesse C. Hill, Knoxville, secretary. Knoxville will be the permanent meeting place, it was said. Among speakers on the program were:

Dr. Willis C. Campbell, Memphis, Surgical Treatment of Arthritis.
Dr. William T. Davis, Washington, D. C., Ophthalmological Symptoms of Endocrine Dysfunctions.
Dr. William D. Haggard, Nashville, Surgery in Goiter.
Dr. Henry G. Bugbee, New York, Diseases of the Prostate.
Dr. William D. Stroud, Philadelphia, Coronary Disease.
Dr. Hugh H. Trout, Roanoke, Prevention of Cancer of the Breast.

Medical Bills in Congress—*Changes in Status* S 2969 has been reported to the Senate, proposing to authorize the deportation of aliens who violate the narcotic laws of the several states, territories and the District of Columbia. S 3060 has passed the Senate, extending the provisions of existing law providing hospitalization and domiciliary care for veterans so as to include men discharged from the Army, Navy, Marine Corps or Coast Guard who are in receipt of pension for service-connected disabilities. H R. 4513 has been reported to the House, proposing to authorize payment of claims for unauthorized emergency treatment of World War veterans when the claims were filed prior to March 20, 1933. H R. 5764 has been reported to the House, proposing to compensate the Grand View Hospital and Dr. Augustus J. O'Brien, Ironwood, Mich., for services rendered to men shot by federal agents during the Dillinger raid on the Little Bohemia Lodge, April 22, 1934. H R. 6995 has passed the Senate, reenacting all laws in effect on March 19, 1933, providing pensions to veterans of the Spanish-American War, including the Boxer Rebellion and the Philippine Insurrection, their widows and dependents. *Bills Introduced* S J Res 169, introduced by Senator Glass of Virginia, proposes to authorize Drs. Hugh S. Cumming, Surgeon General of the United States Public Health Service, John D. Long, medical director, United States Public Health Service, Bolivar J. Lloyd, medical director, United States Public Health Service, and Clifford R. Eskey, surgeon, United States Public Health Service, to accept and wear certain decorations bestowed on them by the governments of Ecuador, Chile, Peru and Cuba. S 3334, introduced by Senator Sheppard of Texas, proposes to provide for the care and treatment of members of the National Guard, Organized Reserves, Reserve Officers' Training Corps and Citizens' Military Training Camps who are injured or contract disease while in military training. H R. 8964, introduced by Representative Clark of North Carolina, proposes to erect a veterans' hospital in the state of North Carolina.

FOREIGN

Personal—Sir Cuthbert Wallace was recently elected president of the Royal College of Surgeons of England, succeeding Sir Holburt Waring.—Sir Ewen Maclean has been elected president of the British College of Obstetricians and Gynaecologists to succeed Dr. John S. Fairbairn.

International Medical Week in Switzerland—Under the patronage of the federal council of Switzerland, an International Medical Week will be held at Montreux, September 9-14. Among speakers listed on the program are:

Dr. Henry E. Sigerist, Baltimore, The Present Unrest in the Medical World.
Dr. Charles Nicolle, Tunis, Hidden Infections.
Sir Henry Dale, London, The Pharmacology of Ergot.
Prof. E. Laqueur, Amsterdam, Male and Female Hormones.
Prof. Max Askanazy, Geneva, The Role of Experimental Studies on Tumors.

In addition to lectures there will be clinics presented by the faculty of the University of Lausanne. Detailed information may be obtained from the secretary, International Medical Week in Switzerland, Klosterberg 27, Basle (*Swiss Journal of Medicine*).

Unemployment and National Health Insurance

The national health insurance system is financed by contributions from the employed, the employers and the government. When it was introduced before the war, no unemployment of the magnitude experienced in recent years was known in this country and therefore was not anticipated. The result of this unemployment has been to derange the finance of the system and deprive a large number of the insured of their title to benefit. The minister of health has therefore introduced a bill which excuses arrears of contributions due to unemployment for the year 1934-1935. Many approved societies have already paid up arrears out of their surpluses. A sum of \$7,500,000 a year is required to finance the bill. The burden will be distributed equally between the taxpayer and the approved societies.

The Lasting Effects of Shell Shock

At a conference on the persisting effects of war neuroses Dr Edward Mapother, medical superintendent of Maudsley Hospital (mental), said that at a low estimate there were approximately 60,000 men suffering from war neuroses. Many of them could work in sheltered conditions but not in competitive positions. There was need for permanent care of those who would need institutional treatment and also for those who broke down under stress and for getting them back to resume work in the world through private industrial colonies. The mental treatment act might well be applied to the foundation of such colonies, which could be a small scale model of something that was a national need.

The End of the Search for a Shaving Brush

Three years ago a consignment of twelve shaving brushes came into Lambeth (a district of South London) and was found to be infected with anthrax. The health officer seized eleven, but the twelfth had been sold and could not be traced. Every one of the eleven was found to be infected with anthrax. The brushes had apparently come from Germany and were sold wholesale at the rate of six for 30 cents. The ministry of health issued a warning concerning the brushes to the hospitals and newspapers in the neighborhood. At last the brush has been found, but unfortunately as the result of a fatality. At an inquest on a boot repairer, who died in the neighboring district of Brixton, the pathologist stated that death was due to anthrax and that the brush was freely infected with the bacilli and spores of anthrax. The health officer gave evidence that a man might use an infected shaving brush every day for two years with impunity until he cut himself and then became infected. The coroner remarked that the only satisfactory feature about the case was the vigilance exerted by the health authorities.

Defense of the Civil Population Against Air Raids

The government has sent to the local authorities the circular on the precautions for safeguarding the civil population against air raids. The use of poison gas in war is forbidden by the Geneva gas protocol of 1925, to which all the most important countries of western Europe are parties, but the possibility of its being used cannot be disregarded. An air raid precaution department has been set up and will give advice to local authorities and the civil population, but local organization is necessary. The construction on any extensive scale of shelters proof against direct hits by bombs is impracticable, because the expense would be prohibitive. But effective protection against blast and splinters from bombs costs little and people can provide it themselves for their households.

PROTECTION AGAINST GAS

Information will be published as to the means by which premises can be made gas proof. Further, the government will accumulate reserves of respirators and protective clothing and will issue them to persons employed on air raid precautionary services. Supplies of bleach powder will also be accumulated for purposes of decontamination. A civilian gas school will be established for training instructors in antigas measures to give training in their own districts. For enrolment and training of emergency personnel, especially for medical and antigas services and instructing the public in air raid precautions, the government has arranged with the Order of St. John and the British Red Cross Society. Arrangements will be made for the decontamination of vehicles, buildings and their contents and contaminated ground, as well as for the organization of expert gas detectors who can determine whether a bombed area is free from gas or requires decontamination.

MEDICAL SERVICES

Provision must be made for the mobilization and expansion of the medical first aid resources of each district, so as to provide first aid posts, casualty clearing stations and hospitals, with an adequate ambulance service. Casualty clearing stations should be within easy reach of first aid posts, but hospital treatment should as far as possible be outside areas of special danger. A series of handbooks on air raid precautions will be issued.

The Prevention of Tuberculosis

At the conference of the National Association for the Prevention of Tuberculosis a number of important suggestions were brought forward. Dr Norman Tattersall, chief clinical tuberculosis officer for Leeds, said that too much stress was laid on malnutrition as evidence of tuberculosis, whereas more often than not the child in danger of active tuberculosis was well nourished and looked well. He suggested that the time had come when every child should have a tuberculin test when he started school. This test should be repeated twice more—once in the middle years and again on leaving school. Every child, not just the positive reactors, should be roentgenographed at the same three age periods. The clinical examination of school children as now carried out was valuable in recognizing malnutrition, rickets, heart conditions and so on but of little practical value in detecting tuberculosis. Dr C. J. Thomas, senior medical officer, and Dr N. D. Bardswell, principal assistant medical officer to the London County Council, in a joint paper declared that the experience of the last twenty-eight years showed that no school medical service in city areas could perform its duties to the children effectively without ample provision for open air education. A most important point in the experience of open air schools was the remarkably complete freedom from attacks of catarrh and colds which the children enjoyed. Councillor Brett of Leeds said that Leeds had gone even further than open air schools and was building a certain number of open air houses—houses with a special bedroom with a large window suitable for tuberculous persons. Professor Christiansen of Copenhagen stated that, while tuberculosis was transmitted from cattle to men mainly by milk, it was also transmitted by direct contact and even through the air. Even if milk infection was effectively prevented there would still remain a lurking danger of transmission from cattle to men until bovine tuberculosis was eradicated altogether.

A New Index of Genera

Since the Swedish naturalist Linnaeus introduced the modern system of zoological nomenclature, several million new species have been named and about 190,000 new genera. For several years the work of systematists has been impeded by the lack of a complete list of the generic names used in zoology. The ground has been partly covered by Sherborn's *Index Animalium* and by annual lists in the *Zoological Record*, as well as by a

work in process of publication by the Prussian Academy of Science. But none of these exhaust the field and it is inconvenient to have to consult several different publications. The Zoological Society has approved a scheme for the preparation of as complete a list as possible of the generic names used in zoology from 1758 to 1935, with references to their sources. It is hoped to publish the work at the end of 1937. Meantime it has been begun under the direction of Dr. S. A. Neave of the Imperial Institute of Entomology and president of the Entomological Society of London, who has had wide experience in zoological bibliography but who hopes to have expert assistance from specialists throughout the world and in particular from the staff of the British Museum of Natural History. The Zoological Society has undertaken to pay for the cost of compilation.

June 28, 1935

Proofs of Efficacy of the BCG Vaccination

There are two methods of proving that the vaccination with the BCG vaccine is efficacious. One method is to cite statistics, the other to show its efficacy by experimental research. At the March 26 meeting of the Academy of Medicine the associate of the late Professor Calmette in the discovery of the vaccine, Professor Guérin, presented the experimental side of the question. He first recalled the observation of Professor Marfan to the effect that persons who presented evidences during infancy of tuberculous lymphadenitis involving the superficial nodes rarely developed pulmonary lesions. Apparently the earlier infection had enabled the individual to build up a resistance to a superadded infection. This observation has served as a starting point for the research on the subject, carried out at the Pasteur Institute of Paris during the past twenty-four years with the object of preventing tuberculosis by vaccination. Experimental work on animals has confirmed the theory on which vaccination is based. Two cows are inoculated with the same dose of a culture of virulent tubercle bacilli. If the first animal gave a positive reaction to tuberculin before the injection and the other animal a negative reaction, the former does not appear to show any ill effects from the injection of the virulent tubercle bacilli, in fact, any preexisting lesions do not seem to be made worse. The second animal, whose tuberculin reaction had been previously negative, dies in fifty or sixty days of a widespread military form of pulmonary tuberculosis. The first animal at necropsy shows only lymph nodes containing virulent tubercle bacilli which kill guinea-pigs inoculated with the macerated lymph nodes. These experiments have been verified by bacteriologists in Austria, Italy and Russia.

Young calves can be given subcutaneous or intravenous injections of the BCG vaccine in doses sufficiently large to be followed by a positive tuberculin reaction without resulting in a generalized tuberculosis. If such animals are given injections of cultures of virulent tubercle bacilli, such as were given to the cows with a positive tuberculin reaction, they also seem to show no ill effects. At necropsy there are no demonstrable evidences of a tuberculous infection except in the lymph nodes, which appear normal but which, on inoculation into guinea-pigs, show the presence of virulent tubercle bacilli. Control calves not vaccinated die of the lesions of military pulmonary tuberculosis in sixty days.

In the case of guinea-pigs and rabbits, Boquet and Nigre have shown that vaccination is followed by well marked but transitory resistance to the injection of virulent tubercle bacilli.

The injection of the BCG vaccine into new-born infants and into adults is followed by a positive reaction to tuberculin. Walgreen of Sweden has succeeded in obtaining this in all of 350 children.

Emphasis was laid on the fact that resistance to tuberculosis is not entirely dependent on a positive tuberculin reaction. The scientific proof of the efficacy of vaccination with the BCG vaccine is that experimentally every allergic animal becomes extremely resistant to superadded tuberculous infection. It confers on both man and the bovine race the ability to react positively to tuberculin. From experimental observation made on allergic cows and calves, one can expect the same results in allergic human beings.

Paris Prepares for Air Raids

About half of the city of Paris was subjected to both day and night tests against potential attacks by air with incendiary and toxic gas bombs. For several hours during the day recently, sirens placed on church steeples and on the tops of high buildings sounded the alarm, so as to test the efficacy of various types of sirens.

The large-scale daytime drills were carried out with complete success in the vicinity of the medical school buildings. Rescues were effected by passive defense workers exactly as they would be in a case of a real attack. Three minutes after the warning shriek of the sirens, "bombs" began falling in the courtyard of the medical school. Several "victims" fell and a fire, consisting of bengal light, broke out. All traffic on adjoining streets was stopped and automobilists had to draw up at the curb, while through the clear space firemen speeded wearing gas masks. First aid workers at the medical school hurried to the rescue of the gas "victims" lying on the sidewalk. Gas masks were speedily slipped over the faces of the "victims," who were placed on stretchers and carried to first aid stations in the basement of the medical school. As the firemen, clad in gas-proof rubber suits, thick gloves and heavy boots, arrived on the scene, further "bombs" began to fall in numerous nearby streets and the red flash of bengal lights broke out on all sides. Gas "victims" were also brought to the first aid stations in gas-proof automobiles. The first aid station at the medical school is equipped with separate rooms, all gas proofed, for the wounded, the burned, and persons overcome by toxic and by mustard gas.

For a half hour during the night, the entire city was awakened by the lugubrious shrieking of the sirens. The half hour was chosen so as to interfere as little as possible with the life of the city. All street, house and automobile lights were ordered extinguished during the trial air raid. Squadrons of planes of all types flew over the city, in order to determine whether important buildings, such as railroad stations, could be distinguished. These observations revealed absolute inability of the planes to identify well known structures in the dark. Physicians were notified that they would be permitted to drive through the streets during the period of darkness, provided they screened their headlights with blue cloth.

Although the danger of war and its accompanying air raids on civilians is fortunately not imminent, every one in the larger cities of France is urged to provide himself with a gas mask. It has been demonstrated that one is safer in the upper stories of buildings than in cellars, because poison gas will seldom reach the level above twenty feet from the ground. Rooms can be rendered gas proof by paper pasted over the edges of windows.

Preoperative Roentgenography in Acute Intestinal Obstruction

The subject of preoperative roentgenography in acute intestinal obstruction has been extensively discussed at recent meetings of the Société nationale de chirurgie. Michel-Béchet has employed the method in twelve cases. In one case, plain films (without a barium sulphate enema) revealed the presence of an S-shaped coil of small intestine near the stomach. A diagnosis was made of obstruction and at the operation a coil of

small intestine was found strangulated in the foramen of Winslow. In the second case the plain film revealed a marked dilatation of a coil of small intestine and a round dark shadow in its midportion. At operation an obstruction due to a biliary calculus was found, thus enabling much time to be saved in the search for the seat and cause of obstruction.

In Moulouguet's paper, attention was directed to the use of preoperative roentgenography, either with or without barium sulphate enemas, in acute ileus. Moulouguet prefers to examine the patient without preparation, but the majority of those who participated in the preceding part of the discussion maintained that this was of much less diagnostic value than with a barium enema. Moulouguet believed that the latter might be employed as a supplementary measure and preferred to examine without preparation before using the enema, because if the plain film revealed marked distention of the small intestine the enema was superfluous. He admitted that gas and fluid in the small intestine were often seen in normal individuals, but except in infants such a finding was of no value in the diagnosis of obstruction of the small intestine. The interpretation of plain films (without a barium sulphate enema) requires considerable experience, but Moulouguet is still certain that plain films with or without the enema, are indispensable in acute obstruction. He expressed the belief that a diagnosis of the seat of obstruction can be made from the plain film without a barium sulphate enema.

First Lectures by Professor Bezançon

Prof Fernand Bezançon, who now occupies the chair of phthisiology rendered vacant by the death of Prof Leon Bernard, will begin a series of conferences on pulmonary tuberculosis, May 10 at the Laennec Hospital Paris.

Committee on Laboratories

In order to determine the qualifications from the medical point of view of those in charge of the many laboratories in Paris a committee has been appointed composed of well known pathologists, bacteriologists and internists.

Fourth French Gynecologic Congress

The fourth annual meeting of the fourth French Gynecologic Congress was held on June 8 at Salies-de-Bearn a watering place that specializes in the treatment of gynecologic disorders. The president of the congress was Professor Buyot. The chief subjects discussed were the etiology and treatment of hemorrhages of general and local origin.

Election of Nonresident Members of the Academy of Medicine

Professor Hopkins of the University of Cambridge, the author of numerous publications on vitamins, and Professor Inada professor of pathology at the University of Tokyo, who has made a study of icterohemorrhagic spirochetosis have been elected nonresident fellows of the Academy of Medicine in the division of biologic sciences.

Death of Professor Jeanselme

Professor Jeanselme, dermatologist of Paris died recently at the age of 77 years. He was a member of the Academy of Medicine professor emeritus at the Faculté de médecine of Paris and attending (emeritus) dermatologist at the Hôpital St Louis. His contributions to the literature of dermatology and syphilis are as familiar as his book on leprosy. Of recent years he had devoted his energies to the history of medicine.

Death of Prof Charles Marie

Dr Charles Augustus Marie chief of service at the Pasteur Institute, died March 29 aged 71. He was the author of numerous papers on vegetable toxins tetanus toxin and epinephrine. An important portion of his research work was devoted to vaccination against hydrophobia.

The Number of German Physicians

According to the statistical report just published, there are 52,342 licensed physicians in the German reich, including the Saar region. It would appear, therefore, that the increases in the medical profession have terminated, for the present. This standstill in the numerical trend is not due to any lack of aspirants. An increase of about 1,400 over the last census was expected, whereas the actual increase is only 125. The physicians who have emigrated to foreign countries, about 1,300 in number, have of course influenced the present status (THE JOURNAL, May 11, page 1766). Of the 52,342 registered physicians, 3,590, or 6.85 per cent, were women (5.63 per cent in 1930, 6.44 per cent in 1932). The percentage of women physicians therefore shows a constant increase, so that now there is a woman physician for every fourteen male physicians. There are 10,595 physicians connected with institutions, not counting those in roentgenologic institutes, laboratories and pathologic institutes. Owing to a temporary dearth of assistant physicians, a considerable number of positions for assistant physicians have been changed into positions for department or chief physicians. The number of nonpracticing physicians also has increased. In 1932 there were 3,015 such physicians, whereas in 1935 the number had increased to 3,679, or 7 per cent of

TABLE 1—Distribution of Specialists in Germany

Specialties Represented	Total Number Representing Each Specialty	Percentage of Specialists Representing Each Specialty	
		1935	1930
Internal diseases	3,862	25.0	24.4
Surgery including orthopedics and diseases of women	2,932	19.1	16.7
Gynecology	1,630	10.6	11.0
Diseases of children	1,178	7.6	8.2
Mental and nervous diseases	1,058	6.8	6.4
Diseases of the eye	1,853	8.8	9.1
Laryngology rhinology and otology	1,517	9.8	10.2
Dermatology venerology and urology	1,905	12.3	14.0

the total number of physicians. This increase is doubtless due not so much to disqualification on account of age as to the fact that numerous non-Aryan physicians have given up their practice. Furthermore, a more exact registration may account for part of the increase. Of the 48,663 male and female physicians connected with institutions or having an independent practice, 15,456 were specialists (which does not include the specialists for physical and dietetic therapy, radiologic diagnosis and therapy, medicomechanics, diseases of the mouth and jaws disorders of the lower extremities, homeopaths and medical directors of athletic associations). The recognized specialists constitute at present 31.7 per cent of the registered practicing physicians (in 1930, 28.9 per cent). Table 1 shows their distribution.

While there has been a general increase in the number of specialists some specialties show an increase (the internists and the surgeons) and others a decrease (the dermatologists and the pediatricians). In the fifty-three large cities with 100,000 or more inhabitants, 49 per cent of the physicians reside and the forty-eight cities with between 50,000 and 100,000 population claim 8.2 per cent. In the whole German reich there is an average of 7.9 physicians for each 10,000 inhabitants in the groups of cities just mentioned, however, there are 12.8 and 12.3 respectively, for each 10,000 inhabitants so that in the communes with fewer than 50,000 inhabitants there are only 5.3 physicians to 10,000 of population. While there is a wide range of difference in the percentage of physicians in the several groups of cities, the distribution of the specialists in the various areas shows but slight differences. For example,

the percentage of specialists in the large cities is almost the same as in the cities with from 50,000 to 100,000 population. On the other hand, the proportion of women physicians in the large cities is 88 per cent, in the middle-sized cities 68 per cent, and in the smaller communes only 47 per cent.

Formerly few physicians emigrated to foreign countries. According to recent statistics, 1,307 physicians have emigrated, which constitutes more than 24 per cent of the medical profession. About two thirds of the emigrants belonged to the 30-45 age group, approximately one tenth were younger, while

TABLE 2—Percentage of Specialists Among the Emigrants Belonging to Each Specialty, Also Among the Physicians Remaining

Specialties	Representation of Each Specialty	
	Among the Emigrants	Among Physicians Remaining
Internists	12.4%	7.4%
Surgeons	5.4%	5.0%
Gynecologists	4.4%	3.1%
Pediatricians	5.6%	2.2%
Dermatologists	6.3%	3.0%
Ophthalmologists		
otologists	3.3%	5.5%
laryngologists,		
rhinologists	63.7%	72.6%
Other physicians		

16 per cent were women. More specialists were among the emigrants than their representation in the medical profession would lead one to expect. Table 2 shows the percentage of specialists among the emigrants belonging to each specialty, and also the percentage of specialists among the physicians remaining.

From Berlin, 572 physicians have emigrated, from Frankfurt-on-Main 59, from Hamburg 58. Table 3 shows the percentage of physician emigrants going to the various countries, in addition, 584 failed to state the country to which they were emigrating.

TABLE 3—Percentage of Physician Emigrants Going to the Various Countries*

Foreign Destinations of Physician Emigrants	Percentage of Physician Emigrants Going to Various Foreign Countries
Africa	2.9
America	18.0
Asia	5.6
Austria	2.6
Czechoslovakia	2.4
England	7.6
France	7.7
Italy	5.0
Netherlands and Belgium	4.6
Northern Europe	3.2
Palestine	33.6
Poland, Portugal and Spain	1.6
Southeastern Europe	4.0
Switzerland	5.8

* Of THE JOURNAL, March 9, p. 847.

Operations on Skull and Brain Lesions

Professor Jentzer, surgeon of Geneva, recently addressed the Münchener ärztlicher Verein on "Operations on Fresh Traumatic Skull and Brain Lesions." He reviewed the material that had accumulated in his clinic during twenty years, and on this basis discussed symptoms that may be regarded as indications for operation. They are unilateral mydriasis, unilateral exophthalmos, incontinence of urine and stool, and traumatic lesion of the meninges at the site of the external lesion. By far the most important symptom is unilateral mydriasis, which is a sure sign of increased pressure on the same side of the brain, even when crossed neurologic symptoms are present. In rare instances an increase of pressure may be produced by a sympathetic irritation from the other side of the brain. In the presence of unilateral mydriasis, observation of the patient is necessary every fifteen minutes, for the mydri-

asis often changes its aspect within that period. It may disappear as rapidly as it came, but it is always a sign of an increase of pressure on the same side of the brain and reveals in most cases a hematoma. Of the trephinations, interventions on the occiput are much more dangerous but cannot be avoided in bulbar lesions. Jentzer found in eight cases of lesions of the bulbus no visible external signs of a lesion of the bulbus, in spite of precise bulbar focal symptoms. If possible, Jentzer resorts to ventricular puncture before every trephination, in order to ascertain the pressure conditions within the cranium. According to Jentzer's statistics, more than 50 per cent of cranial lesions can be cured without operation.

The Robert Koch Memorial

Just as three years ago, in commemoration of the semicentenary of the discovery of the tubercle bacillus, so now, on May 26, in celebration of the year of Koch's death, special ceremonies were organized, which the minister of the interior and the regional health officers were invited to attend. The memorial address was delivered by Professor Kolle, who was a pupil of Koch and whose death has since been announced.

On this occasion the Robert Koch-Stiftung for the combating of tuberculosis, which had been destroyed by the period of inflation, was reestablished. The new organization, however, will be devoted not only to combating tuberculosis but also to other scientific research for the combating of infectious diseases. Donors of substantial sums may possibly become members of the honorary committee or may be permitted to inscribe their names in the so-called Goldenes Buch. Thus far 100,000 marks (\$40,000) has been collected, and further sums are being added from time to time. The basal donation is a gift of a group of Japanese physicians, dating from 1932.

JAPAN

June 29, 1935

Prevention of Epidemic Diseases

Dr. J. Inoguchi, chief of the section on prevention of epidemic diseases of the metropolitan police board, has reported with regard to the preventive measures applied by the central and local governments throughout the country. The number of epidemics introduced from abroad has decreased remarkably of late. There was an outbreak of 205 cases of cholera in 1929, but since then no cases have occurred except four cases in 1932. Only 1,032 cases of smallpox have occurred during the last five years. Typhus still appears in some northeastern provinces, but not more than twenty cases at a time. Epidemic encephalitis also has decreased, but every year about 300 cases appear. On the contrary, dysentery, typhoid and paratyphoid still continue to rage every year to the number of 30,000 or 40,000 cases. Scarlet fever and diphtheria have suddenly increased of late. In 1930 there were 24,582 cases, including both diseases, but in 1934 there were 46,801. Totals for the last five years have been: cholera 4, dysentery 172,432, typhoid 197,267, paratyphoid 25,952, smallpox 1,031, eruptive typhus 38, scarlet fever 50,030, diphtheria 120,249, encephalitis 2,352.

The police try to find the cases early. They have been instructed to follow up the rumors of neighbors, never fail to visit a house where the doctor goes to see patients, closely investigate the family condition of houses where much ice is used, and make an investigation where odors of disinfectants prevail. If students, clerks or workers who leave their houses regularly through the year fail to appear, an investigation should be made. Police who discover a case are given a prize. In 1934, 466 policemen were rewarded for discovering patients.

Since 1924, the board has performed typhoid vaccinations on more than 1,500,000 persons. Of those vaccinated, 1,661 persons contracted typhoid. The effect of this vaccination has been more effective as years pass, in spite of much opposition.

The Benefactor of Japanese Dentistry

It has long been regretted that the man who introduced western methods of dental surgery into Japan died in obscurity. His grave was nowhere to be found for a long time. Dr. Inada's earnest efforts were at last successful, and the benefactor was found to be William Clark Eastlake. According to reports, he was born in 1834 of a noble family in England. When 22 years old he married in America, where he learned dentistry. In 1860, with his eldest son and wife, he came to Japan and practiced dentistry in Yokohama. He had many followers, some of whom went to America when he returned to the United States, that they might study dentistry. He came back to Japan in 1864 and his office in Yokohama had a great reputation, but his residence was in Tokyo and when the foreign settlement was put under strict limitations by the government he alone was allowed to live anywhere he liked, because of his services. He died Feb. 26, 1887, at the age of 54. His grave was found in the Aoyama cemetery in Tokyo. Next year will be the fiftieth anniversary of this first foreign dentist. His biography will be published and a monument will be erected by the members of the dental society of Japan to celebrate his great services.

Standard Technical Medical Terms

The Japanese language society which was formed in 1932, has established a section on medical terms. This section is to endeavor to unify the technical terms in medicine of this country. Through lack of uniformity in medical terms, many misunderstandings have arisen. All branches of medicine are now obliged to standardize their terms in Japanese. The ophthalmologic and gynecologic societies and the anatomic section have already completed the unification of technical terms used in these branches of medicine. The physiologic society is proceeding to do so. The general policy of selecting proper terms is based on the following principles. The selection of terms should adhere to the spirit of the rules adopted by the national language council of the bureau of education and should employ the Chinese character in common use selected by that council. The medical names used by the national resources bureau of the cabinet will be employed as much as possible. As for words of foreign origin, there will be much discussion as to whether the foreign term should be adopted as has heretofore been done or whether it should be translated into Japanese. The only difficulty of this important work is that it has no central authority but the bureau of education will take up this work in due time.

Emperor Honors the Oldest Practitioner in Japan

Dr. Hikomasa Sasagawa has reached the age of 99 years. He was born March 18, 1836 in the northeastern province of this country, the second son of a physician. He came to Tokyo in 1855 to learn medicine and afterward became the adopted son of Dr. Sasagawa in recognition of his sincerity and diligence. After practicing in several places he went back to his native town, where he has been in practice for more than forty years. He is still strong and at present is as busy as a young doctor. He says that only faithful obedience to the laws of health permits one to enjoy longevity and physical strength. The provincial medical association recently held a celebration in honor of his long career and public spirit. The emperor bestowed a gift on him as a token of his sympathy with the aged.

Increase in Automobile Accidents

A rapid increase in automobile accidents has been occurring all over the country, especially in the cities. In 1926 the deaths caused by automobiles numbered about 500 but in 1932 they had risen to more than 1,300. The injured numbered about 13,000 in the former year and 37,000 in the latter. In Tokyo alone in 1934 there were 340 killed and more than 13,000 injured. The victims are usually the poorer pedestrians and the drivers

of taxicabs, who are also generally poor, for in Japan owners of cars do not usually drive them themselves but hire drivers. The urgent need for accident insurance is obvious.

Preservation of a Dying Race

As the race of Ainu is decreasing in numbers, the government has been urged to take measures to protect and preserve the members of the race. In the Iburi districts there are 719 families, including 1,742 men and 1,716 women. Their daily life is quite insanitary, and venereal diseases and tuberculosis are common. The Hokkaido Imperial University is going to establish a health center for examination and treatment. At the same time advice will be given with regard to healthful modes of living.

Experimental Cancer of the Liver

The Cancer Research Society has awarded its annual prize for 1935 to Dr. Tomizo Yoshida of the Sasaki Institute for his success in producing experimentally tumors in the liver. He is reported to be the first man to succeed in producing in the viscera tumor of any kind. He experimented on 300 black rats for months and he is going to make public the details of the experiments before long.

Marriages

JAMES CORNELIUS PASS FEARRINGTON of Winston-Salem, N. C., to Miss Florence McCanness of South Boston, Va., April 17.

THOMAS WALTER LONG NEWTON, N. C., to Miss Thelma Alice Gill of Wake Forest, February 3, announced June 8.

FLETCHER JOHNSON WRIGHT JR., Petersburg, Va., to Miss Martha Jeanette Andrews of Lynchburg, June 29.

JOHN PORTER FLANDERS, Battle Creek, Mich., to Miss Viva Richardson of Lansing, at Keokuk, Iowa, July 7.

ROBERT M. HOLLAND, Boston, to Miss Helen Geary of Waltham, Mass., at Fountain Springs, Pa., June 29.

CLARENCE PORTER JONES JR., Newport News, Va., to Miss Selma Schunk of Sacramento, Calif., April 25.

LAWRENCE RICHARD BANNER, Kalamazoo, Mich., to Miss Rosellen Goiman of Huntington, Ind., June 29.

WILLIAM HOLMAN HANNING, Dayton, Ohio, to Miss Hannah Rebecca Lewis at Chadbourn, N. C., June 18.

WILLIAM O. BEDINGFIELD, Savannah, Ga., to Miss Carolyn Marvin in Yemassee, S. C., June 25.

JOSEPH F. MCGOWAN, Youngstown, Ohio, to Miss Frances Oddi of Yatesboro, Pa., June 28.

ALVIN M. JENSEN, Minneapolis, to Miss Margaret Benson of Center City, Minn., in May.

WARREN COONS CORWIN, University, Va., to Miss Ella Macha of Baltimore, June 22.

CONRAD S. BAKER, New Haven, Conn., to Miss Marjorie Wheeler at Easton, July 23.

ROBERT P. HUDSON, Utica, Miss., to Miss Ruth Fant of Birmingham, Ala., June 30.

PAUL B. BRUMBY, Lexington, Miss., to Miss Lynda Faye Patton of Oxford, June 25.

CORNELIUS F. DUNN, Milwaukee, to Miss Florence Spang of Racine, Wis., June 22.

JOSEPH GREENGARD to DR. DOROTHY HUTCHINSON WELKER, both of Chicago, July 17.

JAMES A. BROWN, Cleveland, N. C., to Miss Jeanette Caldwell at Raleigh, July 8.

ROBERT B. ELLISON to Miss Clarine Wickerham, both of Peebles, Ohio, June 19.

RUSSELL J. BASKETT, Jonesboro, Ind., to Miss Edna Bundy of Spiceland, June 30.

CHARLES ALLEN BORN, Pensacola, Fla., to Miss Vera Blume at Live Oak, June 29.

PAUL R. HINCHEY, Waltham, Mass., to Miss Bessie Hickey of Peabody, June 22.

ARTHUR FLETCHER BALDWIN to Miss Ivy Ludford, both of New York, July 13.

EUGENE C. HEIFETZ to Miss Selma Wahlberg, both of Milwaukee, June 23.

BEVERLY C. COMPTON, Baltimore, to Miss Cynthia Wilson in Chicago, July 6.

Deaths

John Jenks Thomas ♂ Boston, Harvard University Medical School, Boston, 1890, since 1916 professor of neurology, emeritus, Tufts College Medical School and instructor in neurology from 1902 to 1906, assistant professor from 1906 to 1912 and professor from 1912 to 1916, formerly associate in neurology at the graduate school of Harvard University, vice president of the American Neurological Association in 1908, in 1916 and in 1925, president of the Boston Society of Psychiatry and Neurology in 1911, served during the World War, district physician and physician to the Boston Dispensary, 1892-1897, on the staff of the Boston City Hospital since 1893, neurologist to the Children's Hospital, 1913-1919, and since 1919 consulting neurologist, pathologist to the Boston Insane Hospital, 1898-1903, consulting neurologist to the Infants' Hospital and the Quincy (Mass.) City Hospital aged 73, died July 17, in the Phillips House of the Massachusetts General Hospital of strangulated hernia

Frank Allport, Chicago Medical College, 1876, secretary, 1895-1896, and chairman, 1901-1902 of the Section on Ophthalmology of the American Medical Association, for several years chairman of the Committee on Conservation of Vision, and in 1903 member of the House of Delegates practiced for many years in Minneapolis and in Chicago formerly professor of clinical ophthalmology and otology, University of Minnesota Medical School Minneapolis, and at his alma mater, past president of the Minnesota State Medical Association the Chicago Ophthalmological Society and the Chicago Otolological Society, fellow of the American College of Surgeons at one time oculist and aurist to the board of education in Chicago, formerly on the staffs of the Wesley and St. Luke's hospitals, Chicago served in the medical reserve corps aged 78 died August 3, in Nice France, where he had been living for several years

Henry Rockwell Varney ♂ Grosse Pointe Park, Mich., University of Vermont College of Medicine Burlington 1893 in 1907 member of the House of Delegates of the American Medical Association, secretary of the Section on Dermatology, 1909-1912, and chairman, 1916-1917, formerly professor of dermatology and syphilology, Detroit College of Medicine and Surgery, member of the American Dermatological Association, formerly member of the International Congress of Dermatology, city physician, 1896-1899, served on a medical draft board during the World War, at various times on the staffs of the Charles Godwin Jennings Hospital, Harper Hospital and the Children's Hospital, aged 64, died, July 8, of angina pectoris, while on a train en route home from a vacation

Clarence Charles Rice, New York College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1877, member of the Medical Society of the State of New York and the American Clinical and Climatological Association, member and past president of the American Laryngological Association, emeritus professor of laryngology and rhinology, New York Post-Graduate Medical School of Columbia University, on the staffs of the Montefiore Home and Bellevue Hospital, aged 81 died, July 9

William Henry Dudley, Los Angeles, University of the City of New York Medical Department, 1882 University of Southern California College of Medicine, Los Angeles, 1906 member of the American Laryngological, Rhinological and Otolological Society, fellow of the American College of Surgeons, at one time instructor in diseases of the ear, nose and throat, University of California Medical School, aged 80 died, June 9, in Glendale, Calif., of cerebral hemorrhage and uremia

John Hathaway Long, Brooklyn Long Island College Hospital, Brooklyn, 1903 member of the Medical Society of the State of New York fellow of the American College of Surgeons, at one time instructor in surgery at his alma mater, served during the World War, on the staffs of the John Mather Hospital Port Jefferson, N. Y., House of St. Giles the Cripple and Brooklyn Hospital, and St. John's Hospital, Brooklyn, aged 57, died July 14, of cerebrospinal sclerosis

Arthur Hallam Ring ♂ Arlington Mass., Boston University School of Medicine 1897, assistant professor of neurology at his alma mater member of the American Psychiatric Association and the New England Society of Psychiatry, served during the World War served in the neurologic clinic of the Massachusetts Memorial Hospitals, medical superintendent of the Ring Sanatorium and Hospital aged 60 died, June 25, of coronary thrombosis

Levi Harvey Pelton, Waupaca, Wis., Bellevue Hospital Medical College, New York, 1873, member and in 1906 president of the State Medical Society of Wisconsin, past president of the Ninth District Medical Society and the Waupaca County Medical Society, in 1908 member of the House of Delegates of the American Medical Association, aged 86, died June 28, of Raynaud's disease

Harry C. Miller ♂ Omaha, John A. Creighton Medical College, Omaha, 1917, member of the Western Surgical Association, fellow of the American College of Surgeons, surgeon to the Immanuel Deaconess Hospital aged 47, died, June 19, of myocarditis and bacillary dysentery, while aboard the *President Adams* on the Atlantic Ocean

Luis Pablo Pereira y Leal, Rio Piedras, P. R., University of the South Medical Department, Sewanee, Tenn., 1909 member of the Medical Association of Puerto Rico, also member of the House of Representatives of the Insular Legislature, aged 48 died June 15 of cerebral hemorrhage, diabetes mellitus and arteriosclerosis

Arthur Thomas Leopold ♂ Moline, Ill., State University of Iowa College of Medicine Iowa City, 1907, past president of the Rock Island County Medical Society, medical director of the Rock Island County Tuberculosis Sanatorium, Rock Island on the staff of the Moline Public Hospital, aged 50, died July 4

Harry Lovejoy Loop, Saratoga Springs, N. Y. Albany (N. Y.) Medical College 1904 member of the Medical Society of the State of New York formerly secretary of the Medical Society of the County of Saratoga, on the staff of the Saratoga Hospital aged 53 died June 17 of hypertensive heart disease

Alfred Christoph Carl Wiebusch, Steeleville, Ill., Homeopathic Medical College of Missouri St. Louis 1906 member of the Illinois State Medical Society, past president of the Randolph County Medical Society served during the World War aged 54 died suddenly, June 24 of cerebral hemorrhage

William Ernest Hart ♂ Pittsburgh Johns Hopkins University School of Medicine, Baltimore 1909, fellow of the American College of Surgeons instructor in gynecology, University of Pittsburgh School of Medicine, on the staff of the Magee Hospital aged 53 died June 12 of angina pectoris

Cecil Dunmore Murray, New York Columbia University College of Physicians and Surgeons New York 1932 member of the Medical Society of the State of New York served during the World War aged 37 on the staff of the New York Hospital where he died July 4 of Hodgkin's disease

Thurston Hopkins Dexter ♂ Brooklyn Long Island College Hospital Brooklyn 1901, fellow of the American College of Physicians, served during the World War on the staffs of the Wyckoff Heights Hospital, Cumberland Hospital and Swedish Hospital aged 58 died, June 24

Anne Barrett Newton, South Orange N. J., Woman's Medical College of the New York Infirmary for Women and Children, New York 1899 for fifteen years school health inspector, aged 76 died June 17, in the Orange Memorial Hospital, of aneurysm of the aorta

Elmer Sherman Allen ♂ Arcola Ill. Rush Medical College, Chicago, 1895 formerly mayor and president of the school board aged 70 died, June 26 in the Memorial Hospital Mattoon, of meningitis following an injury of the head in an automobile accident

James M. Mattenlee, Sapulpa Okla. Beaumont Hospital Medical College, St. Louis, 1890 member of the Oklahoma State Medical Association, past president of the Creek County Medical Society aged 71, died suddenly, June 25, in Oklahoma City, of myocarditis

Max Sigmund Berk, Brooklyn Columbia University College of Physicians and Surgeons New York 1920, member of the Medical Society of the State of New York, on the staff of the Jewish Hospital aged 40 died, July 2, of rheumatic heart disease

Harry Dickson ♂ Memphis Tenn., Memphis Hospital Medical College, 1909 at one time assistant professor of surgery, University of Tennessee College of Medicine, aged 48, died, June 28, in the Gartly-Ramsay Hospital, of coronary thrombosis

Lowry N. Burchinal Point Marion Pa., University of Maryland School of Medicine Baltimore 1886 member of the Medical Society of the State of Pennsylvania member of the board of education, aged 72 died June 11, of arteriosclerosis

Frederick Elmarian Withee ♂ Newton, Mass., College of Physicians and Surgeons Baltimore, 1892 served during

UNIVERSITY OF WASHINGTON SCHOOL OF NURSING HARBORVIEW DIVISION

451

the World War, for many years school physician, on the staff of the Newton Hospital, aged 70 died, June 29, of heart disease.

George Leininger, Chicago, University of Wooster Medical Department, Cleveland, 1881, member of the Illinois State Medical Society formerly superintendent of the Chicago State Hospital, aged 79 died, July 17, of carcinoma of the intestine.

Charles H Girard, Willimantic, Conn., School of Medicine and Surgery of Montreal, Que., Canada 1890, member of the Connecticut State Medical Society aged 69, died, April 6, of uremia, diabetes mellitus, hypertension and cerebral hemorrhage.

Daniel John Townsend, Lohrville, Iowa Drake University Medical Department, Des Moines, 1887, member of the Iowa State Medical Society formerly member of the state legislature, aged 79, died suddenly, June 3, of heart disease.

William Sheriff Orth & Chicago Rush Medical College, Chicago, 1890, formerly on the staffs of the Alexian Brothers Hospital and the Grant Hospital, aged 70, died, July 16, in St. Luke's Hospital, of cardiovascular renal disease.

Raphael Hector Fabio Piperno, Los Angeles Regia Università di Firenze degli studi Facoltà di Medicina e Chirurgia Italy, 1885 aged 73 died, April 30, of arteriosclerosis, coronary thrombosis and diabetes mellitus.

Arthur Joseph Smith, Boonville, Mo Washington University School of Medicine St. Louis, 1901, aged 59 died, June 20, in the Veterans' Administration Facility, Dayton, Ohio, of arteriosclerosis and heart disease.

John Samuel Boggess & Medical Director U S Public Health Service, Grosse Pointe Park, Mich. Miami Medical College Cincinnati 1898, aged 62, died, June 24, in Detroit, of arteriosclerosis and aortitis.

Jorgen Waldemar Hansen, Manistee Mich., State University of Iowa College of Medicine Iowa City, 1897 aged 64, died, June 15, in the Blodgett Hospital, Grand Rapids, of adenocarcinoma of the rectum.

Augustus Godfrey Beam, Covington Ky Louisville National Medical College, Medical Department State University, 1906 aged 49 died, April 20 in St. Elizabeth Hospital, of cerebral hemorrhage.

Chester De Forest Barnes, Tecumseh, Neb (licensed in Nebraska in 1898) member of the Nebraska State Medical Association aged 68, died, May 25, of myocarditis and bronchopneumonia.

John A Winfrey, Handley, Texas Texas Medical College and Hospital Galveston 1891 aged 72 died, June 29, in the Harris Hospital, Fort Worth of peritonitis and carcinoma of the sigmoid colon.

Edwin Green Greer, Chattahoochee, Ga Atlanta College of Physicians and Surgeons 1912 served during the World War aged 52 died May 13, in Atlanta of bronchopneumonia and emphysema.

Henry Walter Tidmarsh, Whittier, N C North Carolina Medical College Charlotte, 1914 served during the World War aged 45 died, May 8 of insulin shock, diabetes mellitus and myocarditis.

John Silas Booher, Reedsburg Wis Keokuk (Iowa) Medical College, 1896 member of the State Medical Society of Wisconsin aged 71, died July 8 as the result of a cerebral hemorrhage.

Almond Alvah Pratt, Wayland N Y Pulte Medical College, Cincinnati, 1883 member of the Medical Society of the State of New York aged 75 died June 15 of cerebral hemorrhage.

Jacob L Mowery, Strasburg Pa Jefferson Medical College of Philadelphia 1878 member of the Medical Society of the State of Pennsylvania aged 80 died July 4 of cerebral thrombosis.

Frank Loomis Sabin, Newtonville, Mass Boston University School of Medicine 1884 member of the Massachusetts Medical Society aged 78 died May 26 of coronary thrombosis.

John William Lewis, Chicago Bennett College of Eclectic Medicine and Surgery Chicago 1902 aged 61 died, May 22 of septicemia, which developed from a cut on the palm of his right hand.

John Robert Gunne, Dauphin, Manit Canada Manitoba Medical College Winnipeg 1894 M.R.C.S England and L.R.C.P. London 1906 aged 63 died June 5 of coronary occlusion.

William Dyson Kennedy, Lansdowne, Pa Chicago Homoeopathic Medical College, 1884 for many years member and president of the board of health of Lansdowne aged 79 died May 21.

George Wilford McCrary, Seattle, Chicago College of Medicine and Surgery, 1917, served during the World War, aged 47, died, May 6, of heart disease and pulmonary tuberculosis.

John Milton Wells, Chelsea, Mass., University of Oregon Medical School Portland 1890, Bellevue Hospital Medical College, New York, 1893, aged 67, died, July 3, of heart disease.

Hardin Perkins Cochrane, Franklin Tenn., University of the City of New York Medical Department, 1874 Confederate veteran aged 91 died, June 11, of a hip fracture received in a fall.

Franklin Dill Simons, Hermosa Beach, Calif., University of Louisville (Ky) Medical Department 1893, aged 77 died, May 21 of chronic myocarditis arteriosclerosis and hemiplegia.

Harrie Elbridge Hard, Seville Ohio, Western Reserve University Medical Department, Cleveland, 1898, formerly county coroner, aged 64, died June 24, of pneumonia.

William Fuller Harrison, Plains, Pa., Baltimore University School of Medicine, 1904 served during the World War, aged 62 died, June 14, of progressive bulbar paralysis.

Frederick Hayes Sowers & Rochester N Y Trinity Medical College, Toronto, Ont., Canada, 1883, L.R.C.P., London, 1884, aged 76, died, May 27, of arteriosclerosis.

David Houston Chilton, Parrish, Ala Atlanta College of Physicians and Surgeons, 1902 member of the Medical Association of the State of Alabama aged 58 died, June 2.

Robert S Hambleton, Buffalo Hospital College of Medicine Louisville, Ky 1878 aged 82 died suddenly, June 17, of chronic myocarditis and angina pectoris.

Louis Henry Wagner & Cleveland, Cleveland Medical College, 1897, aged 63 died, July 2, in St. Luke's Hospital of hemorrhage due to duodenal ulcer.

August George Berchermann, San Antonio, Texas, St. Louis Medical College, 1875 aged 80, died, June 20, in Billings, Mont., of cerebral hemorrhage.

Clyde Winfield Mummert & Columbus, Ohio, Ohio Medical University, Columbus, 1903 aged 63, died, July 4, in the White Cross Hospital of uremia.

Sereno Marcellus Ferguson, Des Moines, Iowa, Barnes Medical College, St. Louis, 1902, served during the World War, aged 57, died, May 28.

Alphonso Taft Arbuckle, Danville, Ill., Rush Medical College, Chicago 1886 aged 80, died, July 10 in the Lake View Hospital of pneumonia.

James Augustus Bailey, Harrisburg Pa., College of Physicians and Surgeons, Baltimore 1895 aged 63, died July 12 of angina pectoris.

Esther Eleanor Sandus Saunders, Buckbee, Los Angeles, Jenner Medical College, Chicago, 1906, aged 60, died, June 17, of cerebral hemorrhage.

Frank Pierce McLaughlin, Austin, Texas Bellevue Hospital Medical College, New York 1884, aged 80, died, May 25, of myocarditis.

Adolph Arent, Callender, Iowa Rush Medical College Chicago, 1895, aged 62 died suddenly, July 10, of carcinoma of the trachea.

Hubert Miller, Mobridge, S D., Chicago College of Medicine and Surgery, 1909, aged 59, died, July 5, of cerebral hemorrhage.

Thomas J Callan, Detroit, Detroit College of Medicine 1904 aged 63, died, June 11, of carcinoma of the liver and myocarditis.

James Edgar Melton, Los Angeles St. Louis University School of Medicine, 1904 aged 63 died May 8 of bronchopneumonia.

Arthur Moberg, Pittsburg, Kan Marion-Sims College of Medicine, St. Louis 1897, aged 64, died in May, of heart disease.

E Herbert Bailey & Corunna Mich., Detroit Medical College 1884, aged 76 died, June 14, of arteriosclerosis.

Ernest L Dow, Rock Falls Ill Rush Medical College Chicago 1887 aged 73 died, June 29, of heart disease.

Benjamin F Grounds, Blue Ridge Texas Louisville (Ky) Medical College, 1893 aged 71 died, June 10.

Frank H Parker, Rutland Ohio, Columbus Medical College, 1880 aged 79 died suddenly, June 2.

Lewis D Hamilton, Marion Ohio Columbus (Ohio) Medical College, 1881, aged 78, died, May 27.

Alonzo F Christopher, Pearson, Ga., Atlanta Medical College, 1891, aged 82 died April 10.

Bureau of Investigation

DR. W O COFFEE COMPANY

The Mails Are Finally Closed to a Fraudulent Deafness Cure

The Dr W O Coffee Company and its officers and agents as such on June 6, 1935, were debarred from the use of the United States mails because the postal authorities declared that their business was "a scheme for obtaining money through the mails by means of false and fraudulent pretenses, representations and promises"

The history of the mail-order concern exploited under the name of Dr W O Coffee Co is an interesting example of contemporary and near-contemporary quackery * William O Coffee, the originator, has been dead nearly eight years, but for many years prior to his death he was a mail-order quack. He was born in 1859, claimed a diploma from the Missouri Medical College, 1881, and for a while practiced in Blandville and Louisville, Ky, Xenia, Ohio, Janesville, Wis, and Des Moines, Iowa While in Des Moines, he widely advertised a mail-order "eye-cure" business His activities were exposed by Samuel Hopkins Adams in *Collier's* "Great American Fraud" series (1905-1907) In 1915 Coffee filed a petition in voluntary bankruptcy, his heaviest creditor, according to the report, being Arthur Capper, owner of the *Topeka Capital*, which had an advertising claim aggregating many hundreds of dollars

Following his bankruptcy, Coffee for some time carried on an itinerant practice, visiting various towns a day or two at a time In 1918 he moved to Davenport, in which town he again went into mail-order quackery exploiting his mail-order deafness cure He carried full-page advertisements in such papers as were willing to share the profits of quackery Then, Coffee died—Oct 4, 1927 But the W O Coffee concern was much too profitable a business to be permitted to die with him, and it was carried on by Coffee's son P E Coffee, the head of the Dr W O Coffee Company

The records of the American Medical Association show that (1) Percy E Coffee holds a diploma issued more than thirty years ago by a homeopathic school, (2) he has never been licensed to practice medicine in any state in the Union, (3) he has, in fact, claimed to be "not in practice" Obviously, his experience in the treatment of deafness must have been confined to the selling on the mail-order plan of pills and potions to people he has never seen

Reproductions (greatly reduced) of letter heads used by P E Coffee The upper was used for some time following the death of W O Coffee and would lead the public to believe that he was still doing business

So much for past history From the memorandum of the Hon Karl A Crowley, Solicitor of the Post Office Department, to the Postmaster General, in which is embodied the finding of fact and the recommendation that a fraud order be issued, we learn that on March 12, 1935, a copy of the charges to be brought against the Dr W O Coffee Company was forwarded to the concern and it was called upon to show cause

* The Coffee quackery was the subject of a Query and Minor Note in *THE JOURNAL* Jan 26 1918 p 259 It was also dealt with in the article *Deafness Cure Quackery and Pseudo-Medicine* by Arthur J Cramp M D published in *Hygeia* in January 1926

on April 8 why a fraud order should not be issued against it. On April 8 Percy E Coffee, president of the Dr W O Coffee Company (a corporation organized under the laws of Delaware) appeared in Washington accompanied by his attorney, and the case was heard on April 8, 9, 10 and 11 The stenographic transcript of the testimony comprised over 450 typewritten pages, not including many documentary exhibits

Solicitor Crowley in his memorandum states that the Dr W O Coffee Company sold through the mails a treatment for catarrhal deafness, catarrh and head noises.

HARD OF HEARING?

**Send for This 30 Day
Trial Treatment**

Which has restored the hearing, removed head noises and eliminated catarrh of the head for so many people. This is not an internal remedy—but an ethical treatment originated by a prominent ear specialist for his office practice—now simplified for home use This treatment has been used by 1,157,000 sufferers in the past 34 years. Many report remarkably quick results. Write today for full information about our 30 day trial offer We will also send you copies of many letters of recommendation from people whose normal hearing has been restored.

DR. W O COFFEE CO
1356 St. James Bldg Davenport, Iowa

Reproduction of an advertisement sent to the Bureau of Investigation in January 1935 by the superintendent of a state school for the deaf He stated that it was taken from a religious publication, the *Christian Herald*

Mr Crowley brings out some of the facts already mentioned regarding the genesis of the business He brought out, too, the fact that the W O Coffee "treatments" had been changed at various times, and yet in spite of this, P E. Coffee, under the trade name Dr W O Coffee Company, continued to advertise to prospective purchasers that "over one million people have used these medicines" and that the "treatment" was "an absolute duplication (with improvements) of the treatment we used several years ago in our office when we were personally treating patients" Mr Crowley points out that such representations are false, for P E. Coffee during the hearing testified that he had never practiced medicine, but he did state that he had assisted his father for a short time in the latter's office practice by waiting on him as he treated patients

The memorandum brings out further that prospective purchasers were secured through extensive advertising and that P E Coffee spent about \$8,000 a year for such advertising Formerly the advertising had run as high as \$190,000 a year! The Dr W O Coffee Company also circularized lists of names of supposed sufferers from deafness and catarrh ("sucker lists") purchased from letter brokers Coffee sent out so-called diagnosis blanks and stated in his circular letters that if he thought the treatment would help the patient, he would send it, but that if he thought it wouldn't help the patient, he would tell him so Yet he admitted at the hearing that he could not diagnose any case from the answers on the diagnosis blank, and he admitted, also, that he is "incompetent to even make a personal diagnosis of a person suffering from catarrh"! It was brought out, further, that Coffee, in accordance with well established mail order methods, used a follow-up system, sending several letters to individuals who did not bite easily

THE TREATMENT

The Solicitor's memorandum also described in some detail the so-called thirty-day treatment sent out by P E. Coffee. It consisted of

Prescription No 1—This was a powder to be dissolved in a pint bottle of water to be used as a nasal douche a small glass douche accompanying the "treatment" The powder when analyzed by the government chemists

was found to contain principally salt and borax with a small amount of potassium iodide (about 2 1/2 per cent) and a small amount of ephedrine sulphate (about 0.6 per cent). P. E. Coffee claimed at the hearing that this powder also contained oil of eucalyptus, wintergreen, sodium salicylate and benzoate of soda. The government experts developed the fact that the amount of liquid to be used in the douche device was not sufficient to cleanse the nose properly and could not reach or cleanse the nasal pharynx.

Prescription No. 44—This was another powder also to be dissolved in a pint of water and used as a gargle. The powder consisted mainly of boric acid with a small amount of zinc sulphate and much smaller amounts of salicylic acid, carbolic acid, eucalyptol, menthol and thymol. The chief ingredient, boric acid, was present in such small amounts when dissolved in a pint of water that it made a solution of less than one per cent, while the next largest ingredient was present in solution in about one-tenth of one per cent.

Prescription No. 40—This came in a glass tube with a cork at each end to be used as an inhalant. Inside the tube was some cotton saturated with some peppermint oil of eucalyptus oil of mustard and mineral oil. The amount of oil of mustard in the inhalant was sufficient to make the preparation pungent and irritating.

Prescription No. 37—This was an oil, two or three drops of which were to be placed on absorbent cotton and the cotton pushed down into the external ear. The instructions were that the finger was to be held tightly in the ear until the oil made the ear feel warm. Thereafter the cotton was to be removed. The oil according to the government chemists was mineral oil containing some Haarlem oil, alcohol, wintergreen oil of mustard oil of eucalyptus and chloroform. Coffee admitted at the hearing that he had had reports of patients blistering their ears by the use of this preparation, and in such cases he would send **Prescription No. 3** to be used in the place of **37**. This apparently contained no mustard oil.

Prescription No. 48—This was a salve which came in a small tin box. The salve was essentially vaseline or petrolatum, with small quantities of eucalyptus, wintergreen and peppermint oil. The salve was to be inserted up the nose twice a day and at bedtime a small quantity was to be rubbed on the outside of the nose.

Prescription No. 4—This was another ointment also said to be essentially vaseline or petrolatum containing a small quantity of red pepper with some chlorophyll to give it color. This was to be applied behind in front and below the ears and rubbed into the skin until the red pepper began to get in its work.

Dr. Coffee's Veg Erbs—These were laxative tablets (about a dozen to the "treatment") to be used by the patient when he thought a laxative was needed. The government chemists reported that it contained aloin, cascara and podophyllin.

Mr. Crowley, the Solicitor, brings out in his memorandum to the Postmaster General a fact that is common to most mail-order quackery, namely that the representations of the quack begin to change after the victim has once been hooked. In Coffee's first letter soliciting the trial order, the prospective victim was led to believe that the "treatment" would remove the cause of his ear trouble and that about 75 per cent of all persons who use the treatment show improvement in the first month, while many were said to report that their "hearing has been completely restored with one month's treatment." The first letter also discusses the restoration of hearing. However, after the money had been sent to Coffee and the thirty-day trial treatment had been ordered, the victim was advised that he "may not receive any benefit so far as his hearing is concerned with this first month's treatment." This, of course, was to prepare the way for subsequent orders. In subsequent letters Coffee made the statement that "most people expect their hearing to improve with the first month's treatment. This is impossible in most cases." Yet in the sucker bait that Coffee had sent out to catch the victim, he gave the deafened every reason to believe that the first month's treatment would cure 75 per cent of the cases of deafness. Coffee's explanation of this duplicity, according to the Solicitor's memorandum, was that if he were to tell the victims the truth in the first letter and that it would take considerably longer than a month, they would not believe it!

After the victim had paid for his first month's treatment he was sent a second month's treatment together with several letters urging him to send in his "report blank" and to continue taking the treatment. In these letters the victim was advised that many persons required three months' treatment. With the second month's treatment a so-called "Ear Massage Instrument" was sent. This was a small pump equipped with a glass device to be held by the patient against the external opening of the auditory canal to force air against the ear drum. There was also sent in this second month's treatment in place of **Prescription No. 37** another "patent medicine" which was

another ear oil called **Prescription No. 38**. This differed from **No. 37** in that it contained more chloroform. The Solicitor's memorandum then continues:

"Following orders for third, fourth and other treatments, the patient is urged to continue using the treatment and is successively told that many persons require a longer treatment than he has already used.

"The evidence shows that this procedure has been followed even in cases where the patient described at the outset an incurable condition. Dr. Coffee testified with respect to one such case in evidence that the treatment should not have been sent at the outset and that, since no improvement was reported by the patient, he should not have been urged to continue the treatment. He explained that this was due to an error on the part of the girls in his office who examine application and report blanks and fill orders. Dr. Coffee testified that his cheapest inquiries from prospective patients cost him around seventy cents each and that inquiries have cost him as high as \$9 and \$10 each. His interest in urging all patients to continue the treatment is therefore apparent even when statements in letters and report blanks sent in by the patient indicate that his condition is hopeless.

"In one case in evidence where the patient indicated an incurable condition known as otosclerosis, this procedure was followed and four treatments, for which \$40 was collected, were sold. In other cases where patients indicated that they were deaf due to injuries received in football games and had running ears, they were urged to purchase the treatment.

"The representations made by the respondent are calculated to lead the prospective purchaser of this treatment to believe that his case will be diagnosed by a physician from the blanks furnished the company, and that the administration of the treatment will be under the personal supervision of Dr. P. E. Coffee, who the patient is led to believe has had long experience in the treatment of deafness, head noises and catarrh."

Mr. Crowley points out, further, in his memorandum that the evidence during the hearing showed that two women who had been with the W. O. Coffee Company many years were the ones who examined the "symptom blanks" and filled the orders and did not consult P. E. Coffee unless they were in doubt as to whether to send the treatment! In other words, the memorandum shows that P. E. Coffee admitted that it was impossible to diagnose the cases from the symptom blanks he admitted, also, that even if the patient were present, he wasn't competent to diagnose his case, and, finally, it was brought out that he didn't even try to diagnose most cases, but left it to a couple of women with no medical training, who furnished the various "treatments"!

It was also brought out that Coffee testified at the hearing that he declined to furnish any treatment in at least 25 per cent of the inquiries received from prospective victims, yet the evidence showed that when the Post Office inspectors investigated the case and Coffee was called on to furnish all of his advertising, all of his circulars and all of his form-letters, Coffee did not furnish any copy of the form-letter that he submitted at the hearing in which he declined to furnish the treatment. Furthermore, although the Post Office inspectors conducted seven series of test correspondence under assumed names with the W. O. Coffee Company over a period of several years, in which various conditions of apparently incurable deafness were set up in application blanks and letters addressed to the company, in no instance did the W. O. Coffee Company decline to furnish the treatment.

The record was not at all clear as to just what types of cases P. E. Coffee himself did decline to treat. At the hearing Coffee testified on direct examination that in some of the test cases conducted by the inspectors it was proper for him to fill the order, yet on cross-examination on these same cases he stated that the treatment should not have been sent.

Coffee submitted at the hearing fifty-one application blanks which he testified had been declined by sending his form-letter (the first copy of which form-letter was submitted, also, at the hearing). Solicitor Crowley brought out the fact that of these fifty-one applications twenty-two were received by the company about the time that the government took action

in the case, two were undated, and all the balance, with one exception, were received by the company subsequent to June, 1934, when the Post Office inspector who investigated the case interviewed Coffee.

In view of the obvious fraud involved in the Dr W O Coffee business as conducted by P E Coffee, Solicitor Crowley recommended the issuance of a fraud order, which was put into effect June 6, 1935.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address but these will be omitted on request.

ASTHMA

To the Editor—I would appreciate any help that you can give me in the treatment of the most severe case of bronchial asthma I have ever seen. The patient is a woman aged 48 and the mother of two sons 18 and 25 respectively. When about 6 to 10 years of age she had light attacks of asthma which terminated without any special treatment and for a period of about forty years she never had any further asthmatic attacks. About July 1934 frontal sinus infection developed which was treated and did not respond to palliative measures pus developed in the left frontal sinus and was drained through an opening. Later an abscess of the frontal lobe of the brain developed an operation was done in the left temporal region and the abscess was drained with removal of about 1 ounce of pus one week later the pus was drained again from this pocket. The patient improved very much. Her mentality is now normal. The openings drained quite a bit of pus. The temporal drainage ceased after about five months there being very slight drainage from the operation over the frontal sinus at present. About two months after the operations asthma developed which has been most obstinate. The patient has asthma most of the day and night. Some days or nights it is necessary to give epinephrine every three hours and occasionally it does not have any effect on relieving the attacks and only a heavy dose of morphine will give any relief or rest. I have gone into the case as to allergy of foods feathers the dander of animals and so on. These things do not seem to make any difference in the attacks which are most constant unless she is under the influence of epinephrine or morphine. The focal infection of the frontal sinus is probably the cause of the trouble but what I am most interested in is the relief of these attacks. I have also administered hydrochloric acid 1:500 and also 1:1000 intravenously every other day for six doses without any relief whatever. Any treatment you may suggest for relief or cure would be greatly appreciated. I may state that the patient has had ephedrine locally to the nasal cavity and also internally without results. Please omit name and address.

M D Kentucky

ANSWER—The fact that the patient had asthma in childhood should make one suspicious that the symptoms are on an allergic basis in spite of the fact that the recurrence of the asthma was preceded by sinus infection and surgery. Infection of the nasal sinuses per se is rarely sufficient to cause asthma. In the presence of an allergic state or in the previous presence of asthma sinus infection may precipitate attacks of asthma or may aggravate the latter if it already exists. It is evident therefore, that the importance of a thorough investigation of the patient's allergic status cannot be overemphasized. In addition to the tests mentioned this patient should be tested with a number of miscellaneous substances such as house dust, cottonseed, flaxseed, orris root, Karaya gum, tobacco, wood smoke and a number of the common fungi. If an exhaustive attempt at cutaneous tests is of no avail, intracutaneous tests should be done. In the event of failure to elicit any positive response, she should be given a short trial of about ten days with elimination diets (Rowe A H Food Allergy, Philadelphia Lea & Febiger, 1931; Feinberg S M Allergy in General Practice, Philadelphia Lea & Febiger, 1934). If a trial diet does not point to food as an etiologic factor, the patient should be placed in a room as nearly allergen free as possible (directions are given in Feinberg's monograph) for a period of ten days or more.

If no relief is obtained by these methods, it may be at least temporarily presumed that the etiology of the asthma is intrinsic. In this patient, of course the most likely factor of this type would be the sinus infection. If the necessary surgical procedures are completed, the question of bacterial sensitization should be seriously considered. One should prepare a vaccine from the anaerobic and aerobic organisms obtained from the sinus drainage and give subcutaneous injections beginning with semi-weekly small doses and increasing the latter gradually. It is not to be expected that the infected sinuses will be cured in this manner but the sensitiveness to the bacterial proteins may be sufficiently reduced so that clinical improvement in the asthma may result. Other nonspecific means that may be considered

are the use of tuberculin, typhoid protein or B coli vaccine subcutaneously. Artificial fever, by the use of a high frequency current or by typhoid vaccine intravenously, may at times give very satisfactory results. Roentgen therapy to the chest has been successful at times.

From a palliative standpoint a number of procedures are worthy of consideration. The correspondent makes no mention of iodides. If this medication has not been tried, 0.65 Gm doses three times daily should be given. When the patient becomes epinephrine fast or when the frequent use of epinephrine becomes a strain on the nervous system, it is advisable to try sedatives or hypnotics. Practically all men having considerable experience in asthma agree that morphine is inadvisable and dangerous. Equal parts of ether and olive oil given rectally with a small rubber tube may break the habit spasm sufficiently. Usually 60 cc of the mixture is given at the first dose. More may be given later if the first instillation does not suffice. Chloral hydrate or chlorbutanol in hypnotic doses may work in a similar manner. Great care, however, must be used in the administration of these drugs. A simple remedy, but effective and rapid usually, is the inhalation of fumes from the burning of powders containing stramonium, lobelia and potassium nitrate. Several such mixtures are available on the market.

HERNIA OR TERATOID TUMOR

To the Editor—A girl aged 6 weeks with a swelling in the sacral region was operated on at the local hospital. The patient the second in the family was delivered normally. A tumor located between the anus and the coccyx was noticed. It was 11 cm in diameter was rather tense and felt lobulated to about 3 cm at its caudal end. When the child cries it appears more tense while the face and the lips become cyanotic. After ten or twelve days the tumor appeared considerably collapsed, soft and fluctuated like a rubber bag half filled with water. A roentgenogram revealed the fact that the tumor had no connection with the spinal canal and that gas presumably from a piece of intestine appeared in the neck of the sac. Operation showed the sac to be composed of skin and serous lining filled with straw colored fluid. The neck opened into the peritoneal cavity and thence protruded into the colon to just beyond the sac. The opening admitted two finger tips. The base of the sac was considerably thicker with muscle tissue extending to a little over half the height of the sac. The caudal end was lobulated into two 2 cm compartments separated by thin membranes and containing fluid of the same nature. Microscopic section of the sac showed skin on one surface and peritoneum on the other with connective tissue between while the cystic area showed the wall of the cyst to be composed of thin connective tissue lined by flat endothelial cells. I should be pleased to know in your opinion whether this is a congenital pelvis hernia or one of the postnatal intestinal tumors mentioned in Ewing's Neoplastic Disease in the chapter on teratology. I shall also be pleased if you will give a few references from literature relating to this condition.

Tai Wai Wong M D Tungshan Cantoo China.

ANSWER—The wide opening into the peritoneal cavity, the presence of bowel in the neck of the sac, the peritoneal lining, and the covering of skin and muscle suggest hernia. Hernia in this region is by no means frequent, the location in this case would place the hernia if it is one, in the sciatic or ischiatic category, which is one of the rarest of all hernias (Watson, L F Hernia Its Anatomy, Etiology, Symptoms Diagnosis, Differential Diagnosis, Prognosis and Operative Treatment, St. Louis C V Mosby Company 1924, p 475). Cystlike formations may develop in hernial sacs from inflammatory processes.

Another possibility is that it might concern a sacrococcygeal teratoid tumor. Such tumors push the anus forward and lie with their greatest bulk in front of the coccyx and sacrum. In some cases the mass may occupy the back of the sacrum. Teratoma may have fat and muscle, smooth as well as striated, in the wall cysts lined in some cases with flat endothelium in other cases with bowel like mucous membrane, also various vascular components and sometimes nervous structures. The mixture of structures in such tumors led Rindfleisch to speak of a histologic potpourri (Ewing, James Neoplastic Diseases, ed 3, Philadelphia W B Saunders Company, 1928, p 1036).

CALCIUM ACETYSALICYLIC ACID

To the Editor—I have seen several references lately about the use of calcium acetylsalicylic acid in the treatment of chorea. Please give me your opinion of this and also state where the drug can be obtained. I have written several houses but they claim there is no such product.

CARL J SNITKEY M D Belle Plaine Iowa

ANSWER—Recently, in a paper entitled "The Medicinal Treatment of Chorea" (*Brit M J* 2 246 [Aug 11] 1934, abstr *THE JOURNAL*, Oct 6 1934, p 1104), Mutch reported on the use of a product called "Calcium Aspirin." This preparation is stated to be prepared by precipitation from a concentrated aqueous solution of calcium chloride and to have the following approximate composition: $[\text{Ca}_2\text{H}_2\text{O}(\text{COCH}_2)_2\text{CO}_2]_2\text{Ca} + 4\text{H}_2\text{O} + \frac{1}{2}\text{CaCl}_2$. It is doubtful whether such a product is a single chemical entity.

Mutch's paper contains the claim that the drug "supplies an adequate amount of calcium, produces a useful sedative effect on the brain, and combats the rheumatic element if given in appropriate doses." There is no adequate scientific evidence to justify the claims.

Calcium acetylsalicylate, $C_{15}H_{11}O_5Ca \cdot 2H_2O$, has been known for more than twenty years. It has been sold under various proprietary names, at one time it was marketed in England as "Soluble Aspirin," in Holland as "Analutos." The latter preparation was considered by the Council on Pharmacy and Chemistry in 1915 (*THE JOURNAL*, Feb 20, 1915, p 684). While it was claimed to be superior to acetylsalicylic acid because it was more soluble and less liable to produce gastric disturbance, the Council found that the evidence did not uphold these claims. At present the drug is included in the British Pharmaceutical Codex with the statement that its action is "essentially that of acetylsalicylic acid." The chemical and pharmacologic properties of various brands of calcium acetylsalicylate are discussed in a paper by Thompson and Dragstedt of Northwestern University Medical School (*J Am Pharm A* November, 1933 p 1096). In general, calcium acetylsalicylate tablets are less stable than acetylsalicylic acid tablets.

TREATMENT OF MASTITIS BY MEANS OF X-RAYS

To the Editor—What is the present status of the treatment of chronic mastitis with x-rays? Also what is the present treatment of chronic mastitis of the breast and what are the eventualities to be expected in a woman who has had a bilateral excision of the nipples without removal of the parenchyma of the breast? Please do not publish name.

MD Texas

ANSWER—X-rays have been used by some radiologists in the treatment of so-called chronic mastitis and it has been asserted by some that exposure of the mammary gland to x-rays results in the relief of pain. Actually, the method has never been investigated comprehensively and is not generally used.

Owing to the fact that the so called chronic mastitis is probably caused by some dysfunction in ovarian and pituitary hormones treatment of the breasts alone for this condition does not correct the underlying cause. The condition commonly designated as chronic mastitis is actually not an inflammation but a hyperplasia of the epithelium and connective tissues of the breast.

To this condition Sir Lenthal Cheate of London has applied the term *mazoplasia*. Support of the breasts especially when they are pendulous, may be of assistance.

Concerning the question of the eventualities to be expected on one on whom bilateral excision of the nipples has been performed, much depends on the age of the patient and whether or not there is to be subsequent lactation. In the absence of subsequent pregnancy and lactation, there is no evidence that the excision of the nipples will lead to any complications. The reason for this is that dilatation of the ducts and acini is due primarily to an active epithelial hyperplasia rather than to mechanical obstruction, although the latter condition may play some part.

EFFECTS OF SULPHUR DIOXIDE ON THE SKIN

To the Editor—Can you furnish me with any data regarding lesions produced by sulphur dioxide solutions when the hands come in constant contact with the solution? In the problem in which I am interested the sulphur dioxide solution is used in bakery work in order to keep fresh apples from discoloration.

MD California

ANSWER—Sulphur dioxide in the presence of water becomes sulphurous acid H_2SO_3 . One part of water will combine with approximately fifty parts of sulphur dioxide. The strength ordinarily employed in the preservation of fruits is about 5 or 6 per cent. In spite of the avidity of water for sulphur dioxide some of the latter escapes into the air above vats, so that an irritating pungent odor characteristic of sulphur dioxide is commonly present above vats of sulphurous acid. Under conditions of common usage, the strength of the sulphurous acid may increase because of evaporation of water, while the sulphurous acid itself does not readily volatilize. As a result of skin contact an acid dermatitis may be produced. The probability of skin damage naturally increases with the increase in the strength of the acid solution. A dissimilar health problem arises in connection with the consumption of foods that have been treated with sulphur dioxide. For years a controversy has centered about the undesirable effect on dried fruits such as apricots and peaches that have been bleached or otherwise treated by sulphur dioxide gas. When the content of sulphur

compounds in food is below 1,000 parts per million, no injury to the consumer is recognized as likely. Quantities in excess of the amount specified may lead to gastro-intestinal disturbances, nephritis or other conditions. When the quantities exceed 3,500 parts per million, considerable damage is regarded as a reasonable expectancy, whenever the amount of food containing such quantities of sulphur is consumed in fairly large amounts, such as 500 or 600 Gm daily.

DEGENERATION OF SPINAL CORD

To the Editor—A man aged 42 a bank manager complains of numbness and pain in the lower extremities, principally in the back of the thighs the hips and the lower part of the back. The arms and hands are affected to a slight extent. The symptoms began five years ago. The patient had no childhood disease. He crashed as a pilot during the war but cannot remember any definite back injury. Ten years ago he suffered from indigestion and flatulence which lasted about one year. He has had no stomach trouble since. There has been no loss of weight. The tonsils which were definitely infected were removed two years ago. An associated nasopharyngeal catarrh cleared up some months later. The principal points elicited by examination were one large stone in the gallbladder and atrophy of the disk between the third and fourth lumbar vertebrae. Cisternal puncture and examination with iodized oil show some or partial obstruction at the level of the affected intervertebral disk. There is no tenderness on pressure over this area. The teeth are in good condition. The patient had gingivitis of mild type two years ago. The nasal sinuses are apparently normal. The feet are in good condition. The prostate shows evidence of nongonorrheal infection. The patient was treated with massage biweekly for three months with improvement. The Wassermann reaction is negative the hemoglobin 100 per cent. Red blood cells number 5,400,000 white blood cells 7,000. The urine is normal. The specific gravity tends to be high (between 1.025 and 1.027). Neurologic examination is negative. Is gallbladder and nasal sinus infection possible, despite the absence of symptoms? Is laminectomy indicated? The patient is of the introspective type. Kindly omit name.

MD, Canada

ANSWER—If this man has "some or partial obstruction" with iodized oil at the level of the affected intervertebral disk, together with an atrophy of the disk between the third and fourth lumbar vertebrae, two conditions suggest themselves. One is an old injury to the nucleus pulposus associated with an old fracture dislocation of the third or fourth lumbar vertebra. The other condition is a spinal cord lesion either extraspinal or intraspinal. The extraspinal lesion may be a neoplasm (osteochondroma) or arthritis. If there is certainty that there is a definite sign of partial block, the man should have a laminectomy at once. In this type of case one should also find some objective neurologic signs, such as hyperesthesia, hypesthesia, loss or diminution of deep sensibility (bone and joint, position and vibration sense), weakness in one or more parts of either lower extremity, changes in the ankle or knee reflexes, presence of pathologic reflexes (Babinski and others) or sphincteric disturbances. The intraspinal lesion that produces such a picture is subacute combined degeneration of the spinal cord in association with pernicious anemia. In 25 per cent of the cases of subacute combined degeneration of the spinal cord, one does not find a positive blood picture for anemia until later. It is suggested that the stomach contents be examined for free acid. The latter is always absent in combined degeneration of the spinal cord. Gallbladder or nasal sinus infection can produce arthritic changes. In arthritis one rarely, if ever finds a spinal fluid block. Laminectomy is indicated in this case.

GONOCOCCIC INFECTION AND KAHN TEST

To the Editor—On several occasions recently I have received serologic reports on the blood of patients in which the Kolmer reaction was reported as negative and the Kahn reaction as one or two plus. In each of these cases there was no history of syphilitic infection. The pathologist on being consulted raised the question of whether or not there was an active gonococcal infection present. Will you kindly inform me as to whether or not an acute or chronic gonococcal infection could influence the Kolmer or Kahn test as indicated.

L. A. ALESEN MD Los Angeles

ANSWER—Acute or chronic gonococcal infections are not known to affect the reliability of the Wassermann or the Kahn test. One or two plus Kahn reactions and negative Kolmer-Wassermann reactions are encountered occasionally in treated cases of syphilis and less frequently in untreated cases, owing to the somewhat increased sensitiveness of the former reaction. Weakly positive Kahn reactions should be looked on as worthy of careful search for the presence of syphilitic infection. If these reactions are reported by a laboratory with undue frequency, they are probably due to technical errors. Perhaps the antigen is not correctly standardized or the serums are not sufficiently centrifuged to render them thoroughly clear.

ALOPECIA AREATA AND ERYTHEMA AFTER
MOTOR ACCIDENT

To the Editor—Dec 3, 1934 an unmarried woman aged 19, was in an automobile accident. She was riding on the back seat of the car. Following the crash she was unconscious for thirty minutes, having received a blow on the right temporal region. Other than a sprained shoulder and generalized bruises there was no injury of any serious consequence. A week or ten days after the accident she noticed a generalized maculopapular rash. This itched moderately. At the same time her hair began to fall out in bunches. There was a generalized shedding of hair on the body and the inner angles of the eyebrows. The hair of her head is still shedding in fact she is nearly bald. A fine lanugo like hair is appearing. The girl is healthy and robust. She has suffered no illnesses other than those of childhood. She has been quite normal in all respects. Her family history is negative. Her sexual history is negative. A thorough physical examination shows nothing. Laboratory examinations are negative. Repeated Wassermann tests are negative. I still wonder if this condition is secondary syphilis. The rash is still very noticeable. Can psychic shock produce such a picture? Will the girl regain her hair? My treatment is hot oil massages heat and stimulating ointments. Would you suggest another Wassermann test? Any other suggestions will be appreciated. Please omit name.

M D New Jersey

ANSWER—The eruption noted a week or ten days after the accident was, no doubt, a toxic erythema, which could be on a toxic infectious basis or more probably was secondary to sedative drug ingestion administered to allay the pain and restlessness incidental to the accident. The hair loss is of the type seen following nervous shock or emotional stress (Pusey, W A Alopecia Areata and Emotional Stress, *Arch Dermat & Syph* 17 701 [May] 1928).

If the condition were secondary syphilis among other signs in addition to a positive blood serum reaction, there would be infiltration of the papules on the skin, generalized adenopathy, e. g., epitrochlear, posterior cervical and suboccipital, and mouth and anogenital lesions.

There is usually regrowth of hair in cases of alopecia areata, but the prognosis is often grave in the universal cases. The treatment should consist of stimulating medication, as indicated and the relief of the patient from all sources of anxiety. Since reflex irritation may be a contributory factor in some of these cases, attention should be paid to the correction of defective teeth and eyesight. Stimulation of the scalp by varied local treatment should be continued.

AMENORRHEA OF TUBERCULOSIS

To the Editor—In pulmonary tuberculosis one frequently observes amenorrhea. This is of course a true secondary amenorrhea and not specific of tuberculosis. However since the phenomenon of menstruation is undoubtedly a result of the action of hormones one could reason that such an amenorrhea could be the result of a depression of the glands in question by the bacterial toxin and further that titration of body fluids would show a diminution (or altered composition) of the hormones in question. Any enlightenment on this question will be appreciated. Please omit name.

M D Maryland

ANSWER.—The amenorrhea of tuberculosis appears to be identical with the amenorrhea seen in asthenia and malnutrition of nonspecific etiology. Gynecologists frequently see patients referred to them for amenorrhea. If they are alert, they will find the as yet unrecognized lung lesion in a tuberculous patient. On the other hand, innumerable cases of tuberculosis show a normal menstrual cycle and others show an increase of bleeding. Consequently there is no foundation for ascribing the amenorrhea in tuberculosis to a specific effect of the bacterial toxin. Bio assays of the blood and urine in these cases show that they fall into the three groups described by Frank and Goldberger, in which either a subthreshold blood cycle, an absent blood cycle but definite urine cycle, or completely acyclic conditions are noted.

AMINOACETIC ACID IN AMYOTONIA CONGENITA

To the Editor—Would you give your opinion as to whether or not the Boothby treatment is indicated for amyotonia congenita, notwithstanding the teaching that the lesion in myasthenia gravis is in the bulb and also a local lesion of lymphoid cell infiltration in the muscle while in amyotonia congenita the lesion is apparently a failure in the proper development of the lower motor neuron? Please omit name.

M D Montana

ANSWER.—Amyotonia congenita is a rare disease and no reports on the effect of aminoacetic acid in this condition are available. It is quite likely, however, that it might prove beneficial in aiding to overcome the fatigability and muscular weakness of this disease, although it would have no specific effect on the anterior horn cells, which are supposed to be involved in this disease. The fact that the disease has a tendency to spon-

taneous improvement would suggest that aminoacetic acid should be tried in the hope that this improvement might be accelerated.

At present the evidence is in favor of myasthenia gravis being primarily a disease of the muscular system and not of neurogenic origin. Because the bulbar group of muscles is early and characteristically affected in myasthenia gravis, this condition is often mistaken for a true bulbar palsy.

CYSTIC DISEASE OF TIBIA

To the Editor—Five years ago I was consulted in a case of benign bone cyst involving the lower end of the tibia. The cyst had just been operated on at the time, being apparently removed in its entirety. Since then the area of operation has continued to drain. Along with this, another smaller cyst has formed in the upper end of the same bone. This was removed and it also has continued to drain. Recent roentgenograms show what apparently are cystic areas surrounded by healthy bone tissue. The patient has had curettage, roentgenotherapy, chemotherapy, physical therapy, diathermy, bone inlays, wide excision of the area and packing. The blood Wassermann and Kahn tests are negative. Would electrocautery or radical excision of the entire area to include some healthy bone (by means of an electrical saw) help in this case? Maggot treatment has also been recommended. Suggestions as regards treatment are welcome. Please omit name.

M D, District of Columbia.

ANSWER.—Progressive cystic disease, particularly in the tibia, is not altogether rare and is difficult to treat. When an osteomyelitis is present, the problem becomes complicated. The most important element from the standpoint of treatment is the age of the patient, which in this case is presumably under 20, although it is not stated. In refractory cases the entire tibia may be resected subperiosteally. From the thin sliver of periosteal bone left behind, a serviceable tibia will regenerate in young patients. Such a radical operation should not be attempted in adults. The more conservative measure, which can be tried first, is that of maggot therapy. With such conservative measures there is no guaranty that small sequestration will not occur years later, with further sinus formation.

LOCAL ANESTHESIA FOR TOOTH EXTRACTION

To the Editor—Will you please describe for me the technique of giving a local anesthetic for a single tooth extraction? Please also advise how to perform extraction of the molars without breaking off some of the roots. What textbook describes these procedures? Please omit name and address.

M D China.

ANSWER.—There are two methods of giving local anesthesia infiltration and conduction.

To get anesthesia by the infiltration method, it ordinarily takes four injections: two on the lingual aspect of the tooth to be extracted and two on the buccal, the injections being made both mesial and distal to the tooth about 5 mm apically from the margin of the interproximal gum tissue.

Conductive anesthesia is a better method, also more complicated.

Textbooks on these subjects are as follows:

Winter G B Exodontia A Practical Treatise on the Technique of Extraction of Teeth with a Chapter on Anesthesia St. Louis, American Medical Book Company, 1913

Sterling V M Oral Surgery, St. Louis C V Mosby Company 1933

Nevin M and Puterbaugh P G Conduction Infiltration and General Anesthesia in Dentistry New York Items of Interest, 1924

SYPHILIS AND PROSTATIC HYPERTROPHY

To the Editor—A man aged 55 contracted a chancre and gonorrhea about thirty seven years ago. He received some treatment for the gonorrhea but little for the chancre. It was followed by a rash and buboes. Later on he did get a few arsenamine injections and some mercury. He was married and is the father of four healthy normal children. At present he complains of frequent and painful micturition mostly at night, a burning pain running from his head along the spine down to his toes, and forgetfulness especially of recent events. The Wassermann reaction has been positive several times. The last was negative and the spinal fluid was 2 plus. The pupils react to light and in accommodation the knee jerks are normal. The Romberg sign is negative. The prostatic secretion contains pus and gonococci. Kindly discuss treatment in this case. Please omit name.

M D New York.

ANSWER.—The fact that this patient has had little treatment and still has a positive spinal fluid indicates that his syphilitic infection has not been controlled. He should be given some rather intensive treatments beginning with one of the arsenamine preparations and followed up by bismuth and possibly mercury therapy. If the acute symptoms of the prostatic infection have entirely subsided the prostate should be massaged, followed by instillations of silver nitrate solution beginning with 0.5 per cent solution.

PNEUMOCONIOSIS AND LEAD DUST

To the Editor—One of my patients works in an industry that reduces melted lead and tin to fine dust by means of compressed air. The dust from these metals is collected in a large canvas sack. About every two weeks it is necessary for him to enter this large dust-containing sack to gather the lead and tin powder. It fills the air and enters his nostrils. Is this likely to produce pneumoconiosis?

EUGENE F. TRAUT, M.D., Chicago

ANSWER—From theoretical considerations, any damage to the lungs caused by any dust constitutes a pneumoconiosis. Thus, a householder who sifts the ashes from a furnace conceivably might develop a pneumoconiosis, from one day's work, owing to the trivial action of the dust from the ashes. Practically, however, the term pneumoconiosis is reserved for more direful conditions, such as silicosis and asbestosis. This being true, it is unlikely that exposure at intervals of two weeks to a mixed dust from lead and tin would give rise to true pneumoconiosis. It is conceivable that after many years of such exposure a workman might show a slight increase in the amount of fibrosis in his lungs, but the extent of such involvement would probably be unimportant. Lead poisoning is a more reasonable prospect.

ANGINA PECTORIS

To the Editor—I have a patient aged 61 years who was compelled to submit to amputation of his right leg at the middle of the thigh a year ago, following thrombo-angitis obliterans complicated by diabetes and angina pectoris or early coronary occlusion. Seven months after operation he was fitted with an artificial leg. Last November when he attempted to use the new leg his heart condition was aggravated by the exertion and he was obliged to remain in bed for three months. When he is about with crutches any overexertion brings on cardiac pain. He is anxious to attempt to use his limb. Would I be justified in giving my consent for him to do so? Please omit name. M.D., Maryland.

ANSWER.—One would not be justified in allowing the patient described to overexert to the point of inducing attacks of angina pectoris. He should be allowed to get up and gradually increase the amount of exertion, starting with little and increasing by slight increments, always keeping within the limits of what can be done without inducing attacks. He should be put on daily doses of one of the theobromine or theophylline preparations for their tendency to dilate the coronary arteries. Even if there is no immediate result, their use should be continued.

ALOPECIA AFTER ANESTHESIA AND HAIR WAVE

To the Editor—A beauty parlor operator states that hairdressers are taught not to give a permanent wave for at least six months after either as a general anesthetic has been given as the wave does not hold as good, the hair becomes brittle and is liable to cause falling of the hair. Please comment on this. M.D., California.

ANSWER.—The symptomatic form of premature alopecia is of toxic origin, occurring most often some months after childbirth, influenza, typhoid, malaria and such diseases. It is conceivable, though nothing has been found in recent literature on the subject, that an anesthetic or the anesthetic plus the shock of operation might have a similar effect on the scalp. This teaching, then, is an effort of the hairdresser to protect himself against unjust blame for a symptomatic alopecia. It would be wiser for him to refuse to give the so-called permanent wave for six months after childbirth or an attack of influenza, which are much more common causes of toxic alopecia. In fact, if all the possibilities of toxic alopecia are to be considered, few permanent waves would be given.

INTERSTITIAL KERATITIS

To the Editor—I am treating a case of interstitial keratitis due to congenital syphilis in a boy aged 6 years. I began treatment April 16 which consisted of alternating neosarsphenamine and a bismuth compound with 0.5 per cent solution of atropine for eye drops. Since that time there has not been any change in the eyes although the boy's general condition is improving. It seems that there should be more improvement and in the chance that I am overlooking some form of treatment that could give more satisfactory results I am writing to you. If there are any suggestions you can offer I shall be grateful.

GORDON LAWYER, M.D., Cambridge, Ohio

ANSWER.—No, the correspondent is not overlooking anything. The progress of these cases is invariably slow even in the face of vigorous antisyphilitic treatment. From three to six months usually elapses after the institution of treatment before definite results are noted. As a rule the younger the child, the slower are the results to be seen.

Medical Examinations and Licensure

COMING EXAMINATIONS

AMERICAN BOARD OF OPHTHALMOLOGY The Cincinnati examination previously announced will not be held. The next examination will be given in St. Louis Nov. 18. Application must be filed before Sept. 15. Sec. Dr. William H. Wilder, 122 S. Michigan Ave., Chicago.

AMERICAN BOARD OF OTOLARYNGOLOGY Cincinnati Sept. 14. Sec. Dr. W. P. Wherry, 1500 Medical Arts Bldg., Omaha.

AMERICAN BOARD OF PEDIATRICS Philadelphia, Oct. 10 and St. Louis, Nov. 20. Sec. Dr. C. A. Aldrich, 723 Elm St., Winnetka, Ill.

AMERICAN BOARD OF RADIOLOGY Detroit, Dec. 12. Sec. Dr. Byrl R. Kirklin, Mayo Clinic, Rochester, Minn.

ARIZONA Basic Science Tucson, Sept. 17. Sec. Dr. Robert L. Nugent, Science Hall, University of Arizona, Tucson.

NATIONAL BOARD OF MEDICAL EXAMINERS The examination will be held in all centers where there are Class A medical schools and five or more candidates desiring to take the examination Sept. 16-18. Ex. Sec., Mr. Everett S. Elwood, 225 S. 15th St., Philadelphia.

NEW HAMPSHIRE Concord Sept. 12-13. Sec. Board of Registration in Medicine, Dr. Charles Duncan, State House, Concord.

NEW YORK Albany Buffalo New York and Syracuse, Sept. 16-19. Chief Professional Examinations Bureau, Mr. Herbert J. Hamilton, 315 Education Bldg., Albany.

OKLAHOMA Oklahoma City, Sept. 10-11. Sec. Dr. James D. Osborn, Jr., Frederick.

PUERTO RICO San Juan, Sept. 3. Sec. Dr. O. Costa Mandry, Box 536, San Juan.

WISCONSIN Basic Science Madison Sept. 21. Sec., Professor Robert N. Bauer, 3414 W. Wisconsin Ave., Milwaukee.

Arkansas May Examination

Dr. A. S. Buchanan, secretary, State Medical Board of the Arkansas Medical Society, reports the written examination held in Little Rock, May 14-15, 1935. The examination covered 12 subjects and included 140 questions. An average of 75 per cent was required to pass. Forty candidates were examined, all of whom passed. The following schools were represented:

School	PASSED	Year Grad	Per Cent
University of Arkansas School of Medicine (1935)	81 5 81 6 83 83 5 83 8 84 4 84 6 84 7 84 8	(1934)	84 3
Univ. of Tennessee College of Medicine (1933)	80 9	(1935)	79 7*

Nine physicians were licensed by reciprocity from January 12 to May 15. The following schools were represented:

School	LICENSED BY RECIPROCITY	Year Grad	Reciprocity with
Loyola University School of Medicine	(1926)		Illinois
Northwestern University Medical School	(1929)		Iowa
University of Illinois College of Medicine	(1932)		Illinois
State University of Iowa College of Medicine	(1933)		Iowa
Emory Medical College, Missouri	(1908)		Oklahoma
University of Tennessee College of Medicine (1932)	(1933)		Tennessee
Baylor University College of Medicine (1931)	(1933)		Texas

* License withheld until degree is awarded in September

Minnesota April Report

Dr. E. J. Engberg, former secretary, Minnesota State Board of Medical Examiners, reports the oral, written and practical examination held in Minneapolis, April 16-18, 1935. The examination covered 12 subjects and included 60 written questions. An average of 75 per cent was required to pass. Forty-five candidates were examined, all of whom passed. Two physicians were licensed by reciprocity. The following schools were represented:

School	PASSED	Year Grad	Per Cent
Stanford University School of Medicine	(1934)		87 3
University of Colorado School of Medicine	(1933)		84 5
George Washington University School of Medicine	(1933)		89 2

Book Notices

Tuberculosis of the Lymphatic System By Richard H. Miller M.D.
F.A.C.S. Assistant Professor of Surgery Harvard Medical School. Cloth
Price \$4. Pp. 248 with 20 illustrations. New York: Macmillan Com-
pany 1934.

Dr. Miller, in an excellent volume, presents what is known concerning tuberculosis of the lymphatic system. An interesting history of the disease is given. Following this he discusses the bacteriology, pathology, immunity and chemistry of tuberculosis, as well as the modes of entrance and spread of bacilli in the human body. The anatomy of the lymphatic system is treated in detail. Three chapters are devoted to tuberculosis of the cervical lymph nodes, in which he presents the diagnosis and treatment ably and adequately. Tuberculosis of the tracheobronchial and abdominal lymph nodes, the axillary and inguinal lymph nodes and generalized lymph node tuberculosis is dealt with in the remainder of the book. The author places deserved emphasis on the tuberculin test in diagnosis. The immunizing effect of tuberculosis of the cervical lymph nodes has been much discussed by many writers. Miller says: "One must remember that while the tubercles in the lymph nodes in the neck may be conferring on the organism an added degree of resistance, they are at the same time harboring living bacilli which may be set free at any time to be carried to other parts of the body, there to grow in increased numbers. We must be guarded in accepting any such generalization as that tuberculous cervical adenitis may confer any practical immunity to tuberculosis elsewhere in the body. It will give rise to changed reaction and a heightened resistance, but this is probably of not enough actual potency to warrant our accepting it with complacency." He discusses attempts to produce immunity by artificial methods and, particularly, by BCG. Concerning this he says: "One must say that this procedure to obtain immunity is of questionable value and may prove to be distinctly unsafe. It is still sub judice." This book is well illustrated and will be found of much value to every physician interested in the subject of tuberculosis.

Recording of Local Health Work By W. F. Walker Dr. H. and Carolina R. Randolph Division of Health Studies The Commonwealth Fund. In cooperation with the Committee on Administrative Practice of the American Public Health Association. Cloth Price \$2. Pp. 275 with illustrations. New York: The Commonwealth Fund. London: Oxford University Press 1935.

The need for standardization in public health work has long been recognized. The public health field has been perhaps even more individualistic than the private practice of medicine. There have been almost as many administrative patterns for health department work as there have been individual health officers. A few of the more influential workers have developed followers, often through the promotion of those whom they have trained to independent executive positions. In due course of time there developed a multiplicity of administrative procedures and a diversity of records, which made comparison of achievements virtually impossible. Much was accomplished toward correction of this deplorable state of affairs through several agencies, notable among which was the survey of state health departments by Dr. Charles V. Chapin, carried out under the American Medical Association Council on Health and Public Instruction and published in *THE JOURNAL* in 1915; this is probably the pioneer effort at health appraisal. The American Child Health Association made a contribution through its survey of eighty-six cities in 1924 and the U. S. Public Health Service has contributed numerous surveys of public health work in cities and other health jurisdictions. Drawing all this work together and its crystallization into rural and urban appraisal forms for health department practice has been the achievement of the Committee on Administrative Practice of the American Public Health Association. As a logical corollary to the coordination of health practices, a study was made of recording devices and this is now published in the volume under review. Every executive health officer or division director in every health department should have access to this volume. The careful study that has been given to the problems of recording and of compiling usable figures from the records is evident in every page of the work. Full size facsimiles are given for every recommended form. Most health officers would

do well gradually to transform their own system into the standard system, and no health officer can fail to get valuable suggestions from the book. In view of the increasing interest manifested by medical societies in public health problems, the book is recommended also for their consideration.

The Book of a Life From Generation to Generation By J. C. Con-
nell M.A. M.D. LL.D. Cloth Price \$2. Pp. 152. Toronto: Ryerson
Press 1935.

A whimsical medical personage has evaluated critically and philosophically the incidents in the evolution of the individual and has organized them into a diary for life. From birth to 100 years there are blanks for the recording of the major facts including diet defects, disorders, diseases, dimensions, dentition, dental history, immunizations, school record, occupation, sport, travel, recreation, friends, family affairs and financial position. During the first years of childhood appear with surprising authoritative details concerning the height and weight by months and years, eruption of the teeth, and mental development and feeding. Then follow the record of immunizations, which seems thorough except for the omission of whooping cough prophylaxis, record of illness, school status, and posture. When youth is approached, data concerning occupation begin. After 21, account is taken of sports, travel, friends and financial position. Recreation replaces sports at 28, and family affairs loom up at 52. Except for weight, chest and waist measurements, all details are omitted after the 67th year, and the space merely calls for the incidents of the year. Weight continues from 78 to 80, and from this point to 100 only incidents of each year remain on the record.

At the beginning of each year the expectation of life and the mortality rate are announced. Interspersed between the record pages are brief but accurate texts pertinent to the period of life. For instance, in early infancy facts containing growth and development are outlined. A little later communicable diseases, seasonal growth posture and heredity are discussed. Puberty is recognized by data concerning its peculiar growth, and here circulation is first described. At 16, health and periodic examinations are emphasized. At 20 appear a few facts on mental hygiene and soon after data concerning muscular activity, blood pressure and general health. About 30 the question of weight and exercise is answered. At middle life rules of health, prevention of overweight, and dietary advice are elaborated concerning vitamins, food values, and specific diets with typical menus. At 54 the heart and mechanics of old age including exercise, are again recalled. At 64 the essentials of happiness and a common sense discussion of old age and senility appears.

Even if the details are never completed, the book represents a guide for the living without being cumbersome. The rational discussion of exercise begins with the evolution of the baby's effort, childhood games, the sports of youth, the exercise of manhood and womanhood, yielding to "the stage of the easy chair of accomplishment" giving evidence of the advance of age. Follows the couch of senescence and the final repose—the last long sleep.

Every one will be benefited by the hygiene of common sense the writer utters without argumentation. This is a choice book as a gift for all from infancy to "the couch of senescence."

Les colites chroniques. Étude clinique traitement médical et chirurgical. Par M. Chiray professeur agrégé à la Faculté de médecine et de Paris G. Lardennols professeur agrégé à la Faculté de médecine et J. Baumann médecin consultant à Châteauguay. Avec un Exposé de bactériothérapie colitique. Par M. Nicolas chef de laboratoire à la Faculté de médecine. Paper Price 65 francs. Pp. 429 with 47 illustrations. Paris: Masson & Co 1934.

This gives a detailed exposition of the various types of colitis. A classification into mucous colitis, parieto-intestinal colitis, tuberculous colitis, specific colitis and nonspecific colitis has been made. In addition, there are chapters on ileocolic intoxication and sclerosis of the colon. Each of these subjects is thoroughly discussed in individual chapters and treatment is described in separate chapters in the latter part of the book. Under specific colitis are considered those conditions due to parasites such as the ameba, and flagellates, such as *Giardia* and *Balantidium coli*. Colitis due to spirochetes and worms is also discussed. Under etiology of nonspecific chronic ulcerative

colitis, the dysenteries, intoxications and trauma are considered. The pathology of this condition is well described. The importance of orderly, detailed clinical study of cases of nonspecific ulcerative colitis and the importance of their differentiation from all other types of colitis is stressed. The serious complications apt to follow this disease are pointed out. "Mucous colitis" is designated as an inflammatory state of the colon limited to the mucosa and it is stated that this is due to reaction of the mucosa to intestinal content and to abnormal intestinal flora. Treatment is taken up under the headings of general management, evacuation of septic products, modifications of the mucus, vaccine and serum therapy, diet, aids to digestion drugs, nervous symptoms, detoxication, allergic manifestations and distant foci. In addition the management of chronic appendicitis, perityphlitis, chronic pericolicitis, sigmoid diverticulitis, simple sigmoiditis, arteriosclerosis of the intestine and tuberculous colitis and parasitic infestations are considered separately. The discussion of treatment in general is detailed, and many valuable suggestions are offered. Some of the measures of therapy suggested, however, have been abandoned in this country, having been replaced by others giving more satisfactory results. The suggestions for surgical handling of these cases vary greatly from those employed in this country. Questions about the advisability of ileosigmoidostomy, cecosigmoidostomy and the plication operations for redundant portions of bowel could well be raised. These are discussed in detail. It would be worth the while of any one interested in the field of gastro-enterology to read this book.

Clinical Management of Syphilis. By Alvin Russell Barnes M.D. Chief of Congenital Luetic Clinic New York Hospital. Cloth Price \$1.50. Pp 71 with 8 Illustrations. New York Macmillan Company 1935

It is seldom that one will find in a small volume as many misstatements, inaccurate deductions, unscientific and vague clinical impressions and therapeutic misinformation as are found in this volume in the clinical management of syphilis. A few examples are the following. "The primary lesion of syphilis in some instances gives the general appearance of a mild urticaria from which the surface epithelium has been removed." "Many patients in all stages of syphilitic infection complain of 'stomach trouble'." "Patients under treatment for syphilis should take a nap or siesta for an hour or two after their noon luncheon." "Individuals who are infected with *treponema pallidum* do much better when not exposed to the direct rays of the summer midday sun." In referring to diet and hygiene in syphilis the author's favorite dictum is "anything in moderation." Nothing is said about the harmful effects of alcohol and tobacco. Such inaccurate expressions as neosalvarsan hypodermics, Van der Burgh tests and nitroid reactions occur frequently. The discovery of *treponema pallidum* is credited to Schandinn and Hoffmann. The principal features of the book are the treatment tables for the different stages of syphilis in outline or tabloid form, which conform in general to the accepted principles of modern antisyphilitic therapy. The author's advice in nearly every stage of syphilis is to continue treatment uninterruptedly for one year after the blood and spinal fluid tests have become permanently negative. The use of neosarsphenamine as a routine in the management of cardiovascular syphilis is open to question. In discussing visual disturbances during trypanamide medication in neurosyphilis the author states that normal vision will return in practically all cases after trypanamide is discontinued. He states that syphilitic women in the last four or six weeks of their pregnancy should receive arsenicals and not heavy metal compounds. Both of these are dangerous misstatements and are unsupported by clinical experience. Fever therapy with high frequency oscillations is dismissed with the remark that the patient often comes to necropsy and the pathologist's report throws little light on the cause of death. The treatment of congenital syphilis is discussed at somewhat greater length, as the author seems to feel more at home in this department. Nothing is said throughout the book about the danger signs the reactions and sequelae of modern antisyphilitic drug therapy and how these can be prevented and treated. In view of these grave defects and omissions and the obvious fact that the author is not an experienced clinical syphilologist this book cannot be recommended as a reliable guide in the treatment of such a serious disease as syphilis.

Précis de phytothérapie. Essais de thérapeutique par les plantes françaises. Par Henri Leclerc. Third edition. Paper. Price 32 francs. Pp 308. Paris Masson & Co 1935

Apparently a renaissance of "galenism" is on the way, i.e., the use of vegetable rather than of mineral drugs, also a national development, each nation (India, Germany, France) attempting to be as independent of the international drug market as possible. The third edition of Leclerc's volume on the therapy of French plants is an attempt to meet all the exigencies of the healing art as far as possible (and even further) with French herbs. Here, preparations representing the plant in its entirety and in the natural state are to be preferred to active principles. The advocacy of "teas" and of complex mixtures are other manifestations of the swing to primitive methods to which chauvinistic reaction may carry apparently well meaning persons.

Science and the Public Mind. By Benjamin C. Gruenberg. With a foreword by John C. Merriam. President of the Carnegie Institution of Washington. Cloth. Price \$2. Pp 196. New York and London McGraw Hill Book Company Inc 1935

The author deals with the place of science in modern life, including its significance to the layman as a class, to the individual's civic or social interests, cultural interests, the need of education in science, adult interests in science and the content of science for the layman. He then proceeds to consider means and methods of bringing science to the public, with chapters devoted to the teacher the spoken word, including the lecture and the radio, the printing press and sensory and motor aids, such as talking pictures. Finally, he considers the spread of scientific knowledge, science education for adults the public's changing interests and the failure of science to reach the public. He gives four main groups of recommendations for the dissemination of knowledge about science through (a) schools, colleges, university extension departments and other agencies and institutions engaged in educational work in science for adults, (b) museums and similar institutions, (c) academies of science and similar organizations, and (d) research institutions and research units of other organizations. He considers that the needs of the public for science education may be summed up under the following headings: initiative, publicity, cooperation and coordination, stimulation and encouragement, and research. He stresses the importance of continuity and economy of effort by making the most effective use of existing facilities and organizations and he advocates the establishment of some kind of a joint committee for coordinating purposes. The book is a scholarly evaluation of the situation as it exists. The recommendations appear well considered and temperate. For the teacher and the serious student of contemporary problems, this is a stimulating, informative and useful piece of work. There is a satisfactory index.

Supplement to the Eleventh Scientific Report on the Investigations of the Imperial Cancer Research Fund. Under the direction of the Royal College of Physicians of London and the Royal College of Surgeons of England. The Filtrable Tumours of Fowls. A Critical Review. By L. Foulds. Published by the authority of the Executive Committee Boards. Pp. 41. London Taylor & Francis 1934

This is a brilliant critical review on filtrable tumors from 1910, the time when Rous first succeeded in transplanting sarcomas of the domestic fowl, to date. The paper is not suitable for a brief review. An extensive bibliography is appended.

Mount Sinai Hospital Philadelphia Diet Manual. Boards. Price \$2. Pp 73. Philadelphia 1934

The pages are multigraphed and are bound in loose leaf form between paper covers. The volume contains a complete list of therapeutic diets such as are used in a modern hospital. Diets are given in actual food portions as well as in caloric units, and in most instances sample menus are included. Because of its attention to practical detail, this collection should be helpful to the private practitioner in the construction of diets for use in the home. It presupposes, however, a knowledge of the principles involved in the formulation and use of these diets. It is suggested that brief discussion of these considerations preceding each type of diet, as has been attempted in the case of the diabetic diets, would render the volume more suitable for wide distribution.

Injuries and Their Treatment. By W. Eldon Tucker M.A. D.Ch. FRCS Surgeon to St. John's Hospital, Lewisham, Cloth. Price 9/- Pp. 173 with 80 Illustrations. London: H. K. Lewis & Company, Ltd. 1935.

This little volume is not as inclusive in its subject matter as the title would indicate. It is, however, an excellent treatise on the management of acute and chronic sprains, joint injuries, fibrositis, and so on. The text is clearly written with an evident background of wide experience and gives a valuable exposition of the principles of care of these injuries. Particular emphasis is placed on the methods of physical therapy, especially electrotherapy.

Medicolegal

Workmen's Compensation Act Chronic Benzene (Benzol) Poisoning Compensable—Funk was employed by the defendant company in the production of rubber cement tape, in which benzene (benzol) was used as an ingredient. Eventually he contracted chronic benzene poisoning and was awarded compensation by the Minnesota industrial commission. The employer and his insurance carrier brought certiorari to the Supreme Court of Minnesota.

The sole question to be determined said the Supreme Court, is whether or not chronic benzene poisoning is compensable under the Minnesota workmen's compensation act. Section 4327, paragraph 7 subdivision 9 Mason's Minnesota Statutes, provides that "Poisoning by nitro and amido-derivatives of benzene (dinitro-benzol, anilin and others), or its sequelae" shall be deemed to be an occupational disease and compensable if acquired by any worker employed in 'any process involving the use of a nitro or amido-derivative of benzene or its preparations or compounds'. It is conceded said the court that the word 'benzene' was used by the legislature as meaning benzene or benzol, C_6H_6 , and not C_nH_{2n+2} the ordinary benzene. The effects of poisoning from the fumes of the benzene derivatives are usually acute, while those from benzene are characterized as chronic. Did the legislature intend to distinguish between benzene and its derivatives and include the derivatives and exclude benzene as a cause of occupational disease? It is further conceded that benzene poisoning is a typical occupational disease in the general sense and might well have been included in the coverage of subdivision 9. If the legislature intended to exclude benzene, there was no rational basis for the exclusion. The court thought the statutory language declaring compensable "poisoning by nitro and amido-derivatives of benzene (dinitro-benzol, anilin and others), or its sequelae" should be interpreted liberally in connection with the succeeding language, which provides that the poisoning must have been acquired in a "process involving the use of a nitro or amido-derivative of benzene or its preparations or compounds," because the court concluded that the word 'its' evidently refers to benzene and that the word 'preparations' covers mixtures such as caused the workman's disability in the present case.

The court accordingly affirmed the award in favor of the worker—*Funk v. Minnesota Mining & Mfg. Co. (Minn.)*, 256 N. W. 889.

Compensation of Physicians Malpractice Offset Against Value of Services Even Though Statute of Limitations Bars Affirmative Malpractice Action.—The physician-plaintiff sued Wyatt and his wife to recover money due for professional services rendered them over a period of ten years. He did not allege that the defendants had agreed to pay any stated sum but sued on 'an open account'. In their defense, the defendants claimed that the plaintiff had been guilty of negligence in diagnosis and treatment when he treated Wyatt, and they asked that any judgment that might be awarded against them be reduced because of this negligence. The physician-plaintiff demurred to their answers, contending that the defendants' claim of offset on account of alleged negligence was barred by the Colorado statute of limitations, which requires that actions for damages for malpractice be brought within two years of the happening of the malpractice (Session Laws, 1925 p. 342). The trial court sustained the plaintiff's demurrer and

entered judgment in his favor. The defendants then appealed to the Supreme Court of Colorado.

The defendants, said the Supreme Court, by their pleadings tendered an issue as to the reasonable value of the plaintiff's services. They had a right to do so in the absence of any allegation that they had agreed to pay the fixed amount claimed by the plaintiff. They were entitled to have the issue as to the value of the services rendered determined as an issue of fact. Judgment without trial was therefore prejudicial error.

The defendants tendered another issue, kindred to the first one, when they pleaded that in the performance of the services for which he sought compensation the plaintiff was negligent. This issue was not tendered as a counterclaim nor with a view to recovering an affirmative judgment for damages. It was tendered so that against the value of services such as those the defendants had received, rendered normally and in conformity with established standards, there might be offset the diminution in value that resulted from the plaintiff's negligence. In other words, the defendants sought, on account of the damage or loss that they had suffered by reason of the plaintiff's negligence, proportionate recoupment against his claim for compensation.

The Supreme Court called attention to the distinction between, on the one hand, a defense solely by way of recoupment, and, on the other, actions, either original actions for damages or claims for damages made by counterclaims, wherein affirmative judgments against the plaintiff are sought. The statute of limitations, said the Supreme Court, is aimed solely at the maintenance of such actions. Where, as in the present case, the defense presents the question of injury to the defendant in an immediate and vital connection with the services rendered by the plaintiff, whereby the value that the plaintiff seeks to recover for his services is alleged to have been diminished in the very rendition of the services, evidence to prove the alleged injury is admissible, such evidence directly bears on the value of the services, which is the point at issue. The allegations of negligence, like the issue of reasonable value, tender a proper issue of fact.

The judgment of the trial court was reversed and instructions issued as to procedure looking toward a new trial—*Walt v. Burnett (Colo.)*, 36 P. (2d) 768.

- Washington State Medical Association Everett, Aug. 12-14. Dr. Curtis H. Thomson 1305 Fourth Avenue Seattle Secretary.
- Wisconsin State Medical Society of Milwaukee Sept. 17-20. Mr. J. G. Crownhart, 119 East Washington Avenue Madison, Secretary.
- Wyoming State Medical Society Lander, Aug. 12-13. Dr. Earl Whedon 50 North Main Street Sheridan Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to *THE JOURNAL* in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

- Placenta Praevia Complicating Twin Pregnancy. M. W. Haws, Fulton, Ky.—p. 895
- Treatment of Amenorrhea with Large Doses of Estrogenic Substance.—Kurzrok and his associates treated twelve primary and thirteen secondary cases of amenorrhea with large doses of estrogenic substance. They confirm Kaufmann's observation that 40,000 rat units of estrogenic substance is required to produce cyclic bleeding and to build up the proliferative phase of the endometrium. Dosages of 100,000 rat units or more are usually required to bring on the first period in cases of primary amenorrhea, and about 50,000 rat units in secondary amenorrhea. Dosages of 50,000 rat units are necessary to imitate the growth of the breasts mainly the duct system. Dosages of more than 100,000 rat units are essential to produce growth of a hypoplastic myometrium. In some cases of primary amenorrhea the breasts, the cyclic bleeding and the myometrium regressed, in the order named, when treatment

was stopped. The uterine anlage that has failed to develop in the fetus may be brought to some stage of development in adult life by large doses of estrogenic substance. Spontaneous menstruation may follow the cyclic bleeding induced by estrogenic substance (as in secondary amenorrhea). The endometrium that has been built up to the proliferative phase by an external supply of estrogenic substance may be converted to the pregravid phase by the patient's own corpus luteum.

Relation of Vitamin B Deficiency to Metabolic Disturbances During Pregnancy and Lactation.—Tarr and McNeile believe that a deficiency of vitamin B in the diet of pregnant and lactating women usually produces definite symptoms. Signs of demineralization are more pronounced in those women who obtain less than 50 per cent of their total calories from protective foods. It was observed that test cases showed a much better blood picture than was true with the controls. Of the control group, 4.5 per cent were threatened with miscarriage. The test group escaped all such symptoms. More calm and better milk producers were found in the test group. Severe signs of gastric and intestinal atony were almost entirely absent in the test group whereas these signs were encountered in more than 20 per cent of the control group. Undoubtedly this was not purely coincidental. Previous views concerning some of the signs of vitamin B deficiency during pregnancy and lactation have been substantiated.

Infections of Urinary Tract Complicating Pregnancy.—Traut and Kuder deal with the normal changes in the urinary tract accompanying pregnancy and show how these alterations predispose the woman to disease. The uterus, ureters and large intestine undergo an atonic change, which commences during the early months of pregnancy and persists until the eighth month, when it slowly diminishes, so that at term the uterine musculature is not only irritable but contracts vigorously. They have observed much the same reaction in the ureter. As far as the uterus is concerned, this atony of the musculature is a beneficial physiologic phenomenon, being a safeguard against abortion, but in the ureter it constitutes a hazard. In the normal woman the amount of residual urine in the ureter and kidney pelvis varies from 10 to 60 cc., and occasionally in those who have had rapidly repeated pregnancies this may amount to much more, even 200 cc. Residual urine, whether it occurs in the bladder, ureter or kidney pelvis, is a source of danger, as it is prone to infection and, once contaminated, allows of such rapid growth of micro-organisms as to make cure difficult as long as the stagnation persists. *Bacillus coli* is the invading organism in more than 90 per cent of the persons suffering from pyelitis. The onset of the disease is usually after the fifth month of pregnancy and not infrequently in the puerperium, when it is likely to be mistaken for uterine infection. The pathologic picture of pyelo-ureteritis is one of peripheral inflammation of the walls of the ureter and renal pelvis in the earliest stages, with hyperemia and edema as the dominant features. As a more serious pathologic process in the acute phase, there may be extension of the inflammation from the pelvis of the kidney into the peripelvic tissues surrounding the large renal blood sinuses, with the added dangers of blood stream infection. The process may attack the medullary and even the cortical portions of the kidney, in which event these areas are rendered inactive as the result of edema and infiltration of inflammatory cellular elements.

Chlorioneplithelioma with Long Latent Period.—Feiner reports the case of a woman, aged 28, with a vaginal tumor possessing the histologic structure of a malignant chlorioneplithelioma two and one-half years after the last demonstrable pregnancy. In view of the number of well authenticated similar cases reported in the literature, he concludes that in exceptional instances fetal epithelium may remain dormant in the maternal host, either at the placental site or elsewhere, for months or years, then to be stimulated by some unknown agency to malignant proliferation. The fact that many of these cases have developed long after the menopause would effectually disprove the theory that in all such cases an intervening pregnancy has escaped detection. The author regrets that the Aschheim-Zondek test was not utilized earlier in the course of his case, in which event a prompt hysterectomy might have stayed the progress of the disease.

Influence of Exophthalmos on Paretic Ocular Muscles—Bielschowsky states that the rectus muscles of the eyes have, in addition to their principal function, another though subordinate function as retractors, owing to which weakening muscle operations may cause a certain amount of exophthalmos, whereas strengthening operations, such as advancement and resection, leave behind them some exophthalmos. Two cases are reported in which paretic diplopia was combined with exophthalmos. Both anomalies were removed by the strengthening operations. One patient had a disfiguring exophthalmos combined with almost total right ophthalmoplegia due to an orbital operation. Advancement and resection of both the right internal and external recti diminished the exophthalmos considerably and restored binocular single vision in the greater part of the field of fixation. The other patient had exophthalmos and diplopia caused by total paralysis of one superior rectus muscle. Advancement and resection of that muscle, though not restoring its normal function, made diplopia disappear in the middle and lower parts of the field of fixation because the removal of the exophthalmos made it easier to maintain binocular fixation.

Oil Cyst of Orbit with Carcinomatosis—Jones's case of an orbital oil cyst of dermoid origin which had become malignant was found in a middle-aged woman whose left eye had been more prominent than the right for ten years or more, the prominence having noticeably increased during the previous three months. At operation the cyst was ruptured expressing a dark oily fluid. Pathologic examination proved it to contain squamous cell carcinomatous tissue. Heavy doses of radium failed to check the progress of the carcinoma and the patient died with a generalized carcinomatosis.

Intestinal Protozoa in Students—Wenrich and his associates made a survey for the detection of intestinal protozoa in 1 060 students entering a professional school in Philadelphia. Only one stool, obtained without laxatives, was examined for

each of the freshmen, the examinations being made from 1931 to 1933. It was found that 34.5 per cent of these students harbored one or more kinds of protozoa and that 4.1 per cent harbored *Endamoeba histolytica*. The percentage incidence of *Endamoeba histolytica* was higher (5.2) for Philadelphia and its suburbs in Pennsylvania than for other parts of that state (3.4) and for New Jersey (2). Only one of thirty-nine carriers of *Endamoeba histolytica* had traveled "south" in the United States, but six of forty-one carriers had been to Europe. The incidence of *Endamoeba histolytica* in forty-six food handlers was 4.3 per cent. The students harboring *Endamoeba histolytica* appeared to be at least as healthy as those recorded as negative for protozoa, and no cases of amebic dysentery were detected at the institution during the three years of the study. More positives were detected by the study of permanent slides than by the examination of temporary wet preparations.

Studies of Virus and Immune Serum Used in Yellow Fever Vaccination—Theiler and Whitman state that living neurotropic virus, such as is used in human vaccination, multiplies when inoculated without immune serum into susceptible monkeys and is invariably present in considerable concentration in the circulation at some period following inoculation. These monkeys are subject to death from encephalitis. This danger cannot be removed by adjusting the amount of virus inoculated. Infinitesimal quantities are, if anything, more likely to result in encephalitis than larger doses even in the presence of small quantities of immune serum. The inoculation of immune serum shortly before the virus is administered prevents the circulation of virus and yet allows active immunization. It has been shown that the amount of serum necessary relates more to the size of the recipient than to the quantity of virus inoculated. By reducing the virus component 100,000 times, the volume of serum is reduced only five times. The advantages of "hyper-immune" serum have been demonstrated. Very small volumes of highly potent serum are as effective as larger volumes of average immune serum. When the optimal amount of immune serum has been ascertained, a wide range of virus concentration can be used with success. Minimal doses of virus, however, probably fail to produce immunity under these circumstances.

Filtrability of Trachoma Virus—The four experiments of Thygeson and Proctor demonstrate that epithelial scrapings from patients with trachoma contain a virus which is capable of passing through collodion filters impervious to conjunctival bacteria. This virus produces the same type of follicular disease in baboons as that produced by direct inoculation with trachomatous material. The identity of this virus with the etiologic agent of the disease appears more than probable, but the results of animal experimentation in cases of trachoma

must be checked on the human conjunctiva because of the impossibility of accurate diagnosis of trachoma in monkeys or apes. The authors attribute the uniformly positive results in their experiments to the use of epithelial scrapings instead of expressed follicular material and to the use of collodion filters, with resultant minimal loss of virus in the filter due to adsorption. Both morphologic and experimental evidence indicate that the agent of trachoma is an epithelial parasite. The suggestion that the inclusion bodies of trachoma are the result of secondary infection with the agent of inclusion blennorrhea appears extremely improbable from what is known of the epidemiology of inclusion blennorrhea and inclusion conjunctivitis. The possibility of a nonepidemic disease secondarily infecting one half or more of the persons with trachoma seems extremely remote. Even such epidemic infections as conjunctivitis due to *Diplococcus pneumoniae* and *Haemophilus influenzae* complicate trachoma in a relatively small percentage of cases. Furthermore, inclusion conjunctivitis as an independent disease is self limited, having a total duration of from three months to one year. There is no reason to believe that as a secondary infection in trachoma it could increase its duration to coincide with the duration of the trachomatous disease. It appears improbable that the virus of inclusion blennorrhea could be present in all four groups of cases used in the reported filtration experiments.

*Mechanical Production of Cavities in Isolated Lungs S E Moolten New York—p 825

Dissemination of Giant Cells in Lymphoid Tissue in Measles—Hathaway presents a case that came to necropsy in the prodromal stage of measles and in which the characteristic multinucleate giant cells were observed in the spleen and in scattered lymph nodes. The absence of giant cells in the appendical and intestinal lymphoid tissue and mesenteric nodes is further evidence that these cells are rarely seen in lymphoid tissue draining regions in which severe inflammatory changes are present. The giant cells, while numerous in the regions in which they were noted, were not as large and did not contain as many nuclei as some of those described by other observers in tissues removed three or four days before the eruption occurred. The patient was in the late prodromal stage at the time of death, and this fact may account for the stage of degeneration in which the giant cells were seen. The widespread dissemination observed in the patient shows the reaction to be generalized, as one would expect in a generalized infection. Thus far, this type of giant cell seems to be characteristic of measles before the stage of eruption. It is unlike other giant cells in appearance and location. In view of the fact that these cells were first described and their relation to the prodrome of measles pointed out by Warthin and Finkeldey independently, the author proposes that they be called the Warthin Finkeldey giant cells. The case serves to emphasize the point that in cases of the exanthems (measles at any rate) the abdominal symptoms so often present may have an organic basis with serious consequences if left undiagnosed.

Mechanical Production of Cavities in Isolated Lungs—By means of a bronchoscopic punch forceps introduced through the bronchi of isolated unopened human and calf lungs, Moolten produced mechanical laceration and rupture of the bronchial walls and surrounding lung tissue enabling him to remove various amounts of tissue so as to produce gross defects. The underlying principle is laceration of the fibro-elastic framework of the lung followed by inflation. The amount of pressure used for inflation was well within the limit necessary to distend the lung to its maximal physiologic size and in the case of the human lungs was generally a negative pressure of from 20 to 30 cm of water. The size of

the cavities is disproportionate to the degree of laceration or loss of lung substance but depends principally on the amount of pressure during inflation. Regardless of the direction or extent of laceration or the shape of the defect produced by the forcible mechanical removal of pulmonary tissue, inflation invariably results in the formation of one or more smooth-walled, rounded cavities. These experiments suggest that cystic disease, bullous emphysema, saccular bronchiectases and the cavities of tuberculosis or abscess of the lung are products of the same mechanical factors and differ only in degree and distribution.

Hiccup Crisis in *Tabes Dorsalis*—Byrnes believes that the apparent spontaneous onset of hiccup in certain cases of tabes, its periodic occurrence and prolonged duration, its complete cessation when once it is relieved and its not uncommon association with vomiting and epigastric pain supply the characteristics of a true tabetic crisis. Dauncie's suggestion that the hiccup crisis might also be an early, preataxic sign of tabes deserves some consideration. The gastric and hiccup crises have striking analogies, and a prolonged attack of hiccup, in the absence of any discoverable cause, warrants a thorough neurologic examination, and should this not disclose any of the earmarks of tabes, serologic tests of the blood and spinal fluid are indicated. Impulses originating in the last seven thoracic nerves might, either directly or reflexly by means of the phrenic, take part in diaphragmatic contractions. That the phrenic is not essential in the production of hiccup is found in the fact that bilateral phrenic section is not always successful in relieving the symptom. The irritation might be maintained through this lower spinal innervation. The tabetic process has a special predilection for the thoracic cord, and it seems probable that hiccup in this disease is due to abnormal impulses originating in the lower spinal segments. The author thinks that it is through this mechanism that the medicated serum most likely induced the initial and subsequent attacks in his patient by irritation of a system of fibers already partly implicated in the disease. On the other hand, persistent treatment as in the gastric crisis, finally leads to resolution of the original tabetic process. This lower spinal mechanism may take part in the production of postoperative hiccup, as the peritoneum offers a wide field for the origin of impulses that might reflexly initiate abnormal diaphragmatic contractions. Spinal anesthesia might be effectual in relieving this type of hiccup. The promptness with which the symptom ceased in the author's patient on the intradural administration of mercurialized serum suggests that the method is of therapeutic value in its treatment.

Diurnal Variations in Plasma Lipids—Boyd found that normal individuals under usual conditions of life and ingesting three normal meals a day exhibit but slight variations in the concentration of plasma lipids. Samples of blood were taken at intervals of from three to four hours from one morning to the next and analyzed by oxidative micromethods. The standard daily deviation of the results per person was found to comprise, on the average, the following percentages of the means for the day: free cholesterol, 6.5 per cent, ester cholesterol, 7.2 per cent, phospholipids, 9.6 per cent, neutral fats, 22.1 per cent. It was concluded that the concentration of plasma lipids is not consistently or markedly affected by such factors as time of day, intake of ordinary meals and sleep. Variations in the plasma lipids from one person to another were found to be from two to three times as great as the average daily variation per person.

Reducing Action of Dextrose—Wood describes a potentiometric method for studying the progress of an irreversible oxidation-reduction reaction, such as the oxidation of dextrose by ferricyanide. The oxidation of dextrose by an inorganic oxidizing agent, such as ferricyanide ion, is shown to be dependent on the pH of the solution, temperature, salt content of the solution, the concentration of dextrose and the concentration

of the oxidant. A striking similarity is pointed out in the data obtained with ferricyanide and with copper solutions. The reducing action of dextrose is shown to be greatly increased by the presence of sodium cyanide, a fact that offers an explanation of the low blood sugar values obtained with the Folin microcolorimetric method.

Nutritive Value of Lactose—According to Koehler and his associates, the average blood sugar values in sixteen normal young adults after the ingestion of 15 Gm. of lactose per kilogram of body weight showed no important changes, although considerable individual variations were observed. The secondary hypoglycemic effects were lacking. There was frequently a lactosuria present. The ingestion of 15 Gm. of starch per kilogram of body weight caused nearly as much of a peak rise in the blood sugar as obtained after the administration of dextrose. The total hyperglycemia after starch is greater than after dextrose. The average blood sugar values in sixteen obese subjects showed a slight but definite elevation after the ingestion of lactose. The blood sugar changes after the ingestion of lactose in the diabetic patients were marked and of nearly the same magnitude as after the ingestion of dextrose. In the diabetic cases studied, lactosuria was not observed. The average recovery in the urine of intravenously injected lactose was approximately the same (from 89.3 to 93.2 per cent) in normal, obese and diabetic subjects. Ingested lactose caused a small fall in the inorganic phosphate content of whole blood.

Enteritis in Infants—Sauer says that the aseptic, individual nursery technique perfected by Gladys Dick has made it possible to care for 1,620 homeless infants without the occurrence of any cross infection. It is sound economy because it reduces morbidity and prevents unnecessary deaths. A trial of

six years of the Dick diet kitchen and individual, aseptic nursery technic at the Cradle, without cross infection enteritis, proves the technic flawless. The cost is not excessive. The daily per capita cost is less than with the precautionary technic formerly used.

Streptococcus Meningitis in Scarlet Fever—Gordon and Top observe that purulent leptomeningitis is one of the more common intracranial complications, which are particularly rare in scarlet fever. Of 17,311 consecutive hospital patients with scarlet fever, nineteen had generalized streptococcal meningitis. Most instances of streptococcal meningitis originated from primary infection of the middle ear (thirteen), infected paranasal sinuses were a less common source (four), and two originated from localized suppurative infection of a joint with subsequent hematogenic dissemination to the meninges. The case fatality rate for scarlet fever meningitis is high. Only one of the nineteen patients in the series survived. Among the many patients reported by others in the course of years, only six are known to have recovered. No known therapeutic measure offers much promise. The principles of management include removal of the original source of infection, attempted sterilization of the blood stream because general sepsis is often associated, and finally attempted sterilization of the infected meninges. Repeated drainage of the cerebrospinal fluid is a procedure worthy of adoption. Intrathecal administration of antistreptococcus serums and various chemotherapeutic agents has been disappointing.

Antirachitic Value of Irradiated Evaporated Milk—From the study of twenty-three male Negro infants, Rapoport and his associates found that irradiated evaporated milk containing 125 U S P units of vitamin D to a 14½ ounce can appear to be an adequate agent for the prevention of rickets in infants. In two of the infants, who showed no roentgen evidence of rickets at the time they were put on irradiated milk, mild roentgen evidence of rickets developed after the change. These signs disappeared rapidly while they continued to receive the same irradiated milk. The study also indicated that the irradiated evaporated milk appears to be unreliable for the cure of rickets in infants. Although there were two infants who showed complete healing, three infants slight healing, and two infants an advance in the rachitic process followed by slight healing, nevertheless there were four infants who showed no healing and two infants in whom the rachitic process actually advanced without healing. It is possible that the last two infants fall in that group which is refractory to antirachitic therapy, since one of them gave no evidence of healing even after ten days of therapy with 15 cc. of cod liver oil daily. The data do not warrant any conclusions concerning the relationship between the severity of the rachitic process, the rate of growth in length and weight and the amount of antirachitic agent administered, as noted by Wilson. No conclusions could be drawn as to the variation in antirachitic value for infants of different antirachitic agents containing an equivalent number of vitamin D units by rat assay.

Experimental Studies in Alcoholism.—Fleming and Reynolds tested the influence of various substances and procedures (diathermy epinephrine insulin caffeine, carbon dioxide oxygen olive oil physiologic solution of sodium

chloride and magnesium sulphate) on the concentration of alcohol in the human blood stream after intravenous administration of alcohol. The maintenance of an elevated body temperature by diathermy apparently caused an increased rate of disappearance of alcohol from the blood, none of the other procedures tried had any effect that could be considered significant.
